188 LYMPHOGRANULOMA VENEREUM

Albert Heyman

Definition Lymphogranuloma venereum is a virus disease usually transmitted by sexual contact and characterized by a small primary lesion regional lymphadenitis and constitutional symptoms The disease is known by a variety of names such as *lymphogranuloma inguinale lymphopathia venereum* and *climatic bubo* but the name generally preferred is *lymphogranuloma venereum* This disease should not be confused with granuloma inguinale an ulcerative infection of the skin caused by the Donovan body (p 916)

Etiology The etiologic agent of lymphogranuloma venereum is a comparatively large virus When stained by special methods the organism can be seen with the ordinary microscope as small spherical granules or elementary bodies The virus is also distinctive in that it is susceptible to sulfonamide therapy It produces meningoencephalitis in mice and monkeys and can be cultured in the yolk sac of the chick embryo Infected yolk sac tissues are used as diagnostic antigens for intradermal (Frei) tests and complement fixation reactions There are serologic cross reactions however with psittacosis and certain other viruses (meningopneumonitis feline pneumonitis)

Incidence Lymphogranuloma venereum exists in almost every part of the world but is especially prevalent in tropical and subtropical countries It is frequently seen in the southeastern portion of the United States particularly among Negroes There is no accurate information regarding the incidence of the disease Only 880 new cases were reported in the United States in 1955 but it is likely that the incidence is much higher

Pathogenesis Lymphogranuloma venereum is nearly always transmitted by sexual contact The incubation period varies from 2 to 30 days A small evanescent lesion may appear at the site of inoculation but more often the first sign of the infection is inflammation and suppuration of the inguinal lymph nodes The virus is apparently disseminated throughout the body by way of the blood stream it has been isolated from the primary lesion the regional lymph nodes the blood and the spinal fluid Severe systemic manifestations such as meningoencephalitis keratitis cutaneous lesions and arthritis may occur Specific evidence of immunity to the virus including skin sensitivity of the tuberculin type and complement fixing humoral antibodies can be demonstrated in almost every patient shortly after the onset of the disease Positive skin and complement fixation reactions persist for several years Patients with lymphogranuloma venereum frequently have an increase in the globulin fraction of the blood Following the initial infection the patient may remain asymptomatic for a long period of time but may eventually develop late manifestations of the disease such as rectal strictures or elephantiasis of the genitalia

The early histologic lesion of lympogranuloma venereum consists of a granuloma forming about a small blood vessel and composed of large mononuclear cells The vessel is eventually compressed and obliterated and necrosis occurs in the center of the granuloma Polymorphonuclear leukocytes enter the area and an abscess develops The stellate abscesses which are thus formed are characteristic of the fully developed acute lesions of this disease

Clinical Manifestations The initial lesion of lymphogranuloma venereum is seldom noted since it is transitory and inconspicuous Those which are observed consist of single small shallow ulcerations on the external genitalia Shortly after the appearance of the initial lesion there are enlargement and suppuration of the regional lymph nodes The usual site is the inguinal or femoral region and this lymphadenitis is called the *bubo* The typical lymphogranuloma bubo develops slowly is bilateral and forms an ill defined lobulated mass Suppuration usually follows producing multilocular areas of fluctuation which may rupture spontaneously forming one or more draining fistulas

The majority of patients with buboes show constitutional reactions headache malaise fever and anorexia The systemic symptoms and buboes may subside spontaneously and may be the only clinical manifestations of the disease Occasionally the virus causes inflammation of distant areas and aseptic meningitis pericarditis and conjunctivitis have

Manifestations Systemic symptoms are usually mild consisting of headache fever and malaise which subside within a few days Shaking chills and fever as high as 104 F can occur but are unusual A transient macular or vesicular rash which subsides within 48 hr is rarely present during the early stages Erythema nodosum has been reported in one case

In a typical case the *primary* lesion consists of a raised slightly tender papule crowned by a small vesicle or eschar it often resembles an indolent furuncle or insect bite Multiple primary lesions have been described Some patients do not exhibit a lesion

Regional adenopathy becomes evident in from a few days to as long as 6 weeks after infection The axillary and epitrochlear femoral or (most commonly) the cervical nodes on one side become visibly swollen and tender often with redness of the overlying skin The nodes occasionally suppurate soften, and drain spontaneously fistulas always heal completely with only slight scarring Usually the tenderness subsides gradually and nontender firm enlarged nodes remain palpable for some weeks or even months There is no generalized glandular enlargement and the spleen is not palpable

It seems probable that clinical forms of this infectious disease other than that described above may be delineated A few cases of *encephalitis* associated with localized adenopathy and a positive skin test have been reported European authors have suggested that *nonspecific mesenteric lymphadenitis* in children is an abdominal form of cat scratch disease and in at least one reported case a previously negative skin test became positive after an illness diagnosed at laparotomy as mesenteric adenitis A number of cases of so-called *Parinaud's oculoglandular syndrome* characterized by conjunctivitis and regional lymphadenopathy and previously thought to be due to infection by *Leptothrix* have been reported to show positive skin tests for cat scratch disease Evidence for a primary *pulmonary* form is scant but suggestive Specific diagnosis is made by means of a skin test Antigen for this is prepared from pus aspirated from infected nodes it is inactivated by heating at 60 C for 2 hr A positive reaction is of the delayed tuberculin type appearing in 24 to 48 hr Patients in this country have reacted to antigens prepared from European countries and vice versa—evidence that the disease is widespread and that strain differences in skin test antigens are not significant Skin reactivity to the antigen persists for at least 4 years after the disease The Frei test is negative The leukocyte count is usually normal occasionally reaching 13 000 There may be some increase in eosinophils but this is not prominent The erythrocyte sedimentation rate is usually elevated In one reported case serum globulin was elevated early in the disease decreasing with convalescence (reminiscent of lymphogranuloma venereum) and in another a biologic false positive serologic test for syphilis was noted The histologic picture in excised nodes is that of a granuloma with microabscess formation although not diagnostic the pathologic findings are characteristic enough to suggest the possibility of the disease

Cat scratch disease is a benign illness and the prognosis is uniformly good Its main clinical importance lies in its possible confusion with other more serious diseases of the lymphatics Diseases to be considered are tularemia lymphatic tuberculosis sporotrichosis lymphogranuloma venereum and bacterial adenitis Because of the indolent character of the adenopathy Hodgkin s disease or other lymphomas may be suspected Appropriate serologic and cultural tests serve to rule out other infections biopsy may be needed to exclude tumor but a positive skin test with cat scratch antigen effectively rules out the necessity for such procedures

Treatment In instances of node suppuration aspiration of accumulated pus affords relief of pain (and incidentally serves as a source of material for the preparation of skin test antigen) Penicillin and streptomycin are ineffective Tetracycline drugs appear to shorten the course of the disease appreciably but their effect is usually not dramatic

191 HEMORRHAGIC FEVER

J E Smadel

Definition Hemorrhagic fever is an acute illness characterized by fever of 5 days duration accompanied by prostration anorexia and vomiting Capillary abnormalities appear early in the illness they are intensified about the fourth day when petechial hemorrhages become prominent and increased capillary permeability results in marked proteinuria and transudation of plasma constituents into some soft tissues With the termination of fever some patients proceed to recovery but about 20 per cent develop hypotensive shock and renal insufficiency The mortality rate is about 5 per cent No specific laboratory test is available hence the

bites often pass unnoticed Cases occur most frequently in the spring and early summer when ticks are most prevalent The principal vector in the western United States is the wood tick *Dermacentor andersoni* the only tick in this area which commonly feeds on man In some heavily infected areas of the West as many as 14 per cent of ticks carry the virus

Manifestations The *incubation period* is 3 to 6 days Illness appears abruptly with chills or chilly feelings rapid rise in temperature to 102 to 104 F *unusually severe headache muscular aching photo*phobia malaise nausea and considerable prostration These symptoms continue for 1 to 3 days after which the temperature returns to normal and the patient feels nearly well After an interval of 1 to 3 days the fever returns and the same symptoms reappear though sometimes in a milder form This episode also lasts for 1 to 3 days and then the patient recovers Occasionally one sees single *or triple episodes of pyrexia but the typical tem*perature curve presents a distinctive saddleback configuration There are no abnormal physical findings in the usual cases other than those related to fever Convalescence is well established by the end of 7 to 10 days There have been indications that the disease is not always so benign as was formerly thought Several authenticated cases of encephalitis have been seen with abnormal neuro*logic signs and spinal fluid findings*

Laboratory Findings The white blood cell count is helpful in diagnosis as there is a leukopenia which is most marked during the second febrile period Total leukocyte counts of 2 000 to 3 000 per cubic millimeter are common The percentage of polymorphonuclear leukocytes is less than normal and there is a shift to the left Viremia is present throughout both febrile periods as well as *during the remission Complement fixing and neu*tralizing antibodies can be demonstrated in the serum for 10 to 30 days after onset of illness

Differential Diagnosis The disease was originally thought to be a mild variety of Rocky Mountain spotted fever and there is still considerable confusion because of the fact that both are tick borne and both occur in the Rocky Mountain region The initial manifestations of Colorado tick fever are not very distinctive in fact they are common to many viral and rickettsial infections such as influenza psittacosis viral encephalitis typhus and Rocky Mountain spotted fever The symptoms saddleback fever and leukopenia bear a striking *resemblance to dengue but the latter is accom*panied by an eruption and is found in a different geographic area

Treatment The known antibiotics are without value and there is no specific treatment Analgesics and sedatives are used for alleviation of symptoms

Prognosis No relapses are seen and no deaths have been reported Recovery is followed by prolonged *probably lifelong active immunity*

190 CAT SCRATCH DISEASE

Ivan L Bennett Jr

Definition and Etiology Cat scratch disease is a specific infection characterized by indolent occasionally suppurative regional lymphadenitis secondary to a primary cutaneous lesion at the site of inoculation usually a minor trauma Because more than half of the reported cases have originated from *cat scratches and a history of close contact* with cats is often elicited the name *cat scratch disease* has become popular However the disorder has been acquired from splinters thorns beef bone fragments etc and in a fair percentage of patients no inciting trauma is recalled Other names such as *nonbacterial regional lymphadenitis* or *benign inoculation reticulosis* have been suggested but have not been widely used

A specific etiologic agent has not been identified Bacterial cultures of involved nodes are uniformly negative The disease has been transmitted by inoculation of pus from suppurating nodes into monkeys and man but numerous attempts to isolate a virus have failed Intranuclear and *intracyto*plasmic inclusions are seen in histologic preparations of infected nodes furthermore complement fixing antibodies for lymphogranuloma venereum antigen are occasionally demonstrated in sera of patients with this disease These suggest that a virus perhaps related to the lymphogranuloma psittacosis group may be the causative agent

Careful observation of cats thought to be re*sponsible for the disease has revealed no evidence* of illness these animals do not react to intradermal injection of antigen These facts together with the evidence that other forms of trauma transmit the disease may indicate that the infecting agent is *simply transmitted passively by the cat s claws*

fifth to seventh day after onset or progressive renal failure during the second week or both The acute renal failure is in no way unique in regard to its clinical manifestations hence this phase needs no further discussion here (see p 1367) The physical findings in the shock phase are those of peripheral vascular collapse In spite of the marked lowering of blood pressure the skin is warm and flushed The loss of plasma through damaged capillaries and pooling of blood in dilated peripheral and visceral capillaries result in reduced circulating blood volume All these abnormalities contribute to the profound dysfunction of selected organs such as the kidney

Laboratory Findings and Pathology Clinical laboratory data other than those already mentioned consist of (1) leukocytosis of 10 000 to 20 000 per cubic millimeter with many immature granulocytes by the end of the first week (2) thrombocytopenia which reaches levels below 100 000 in half the patients (3) disturbances of electrolyte balance and (4) entirely negative results in various types of tests for the ordinary microbial agents

The characteristic lesions observed at autopsy are found in the kidney right auricle and pituitary gland The renal cortex is pale while the pyramids are dark red almost hemorrhagic in appearance Hemorrhages occur in the auricle and pituitary gland If death ensues during the hypotensive phase gelatinous edema fluid is found in the retroperitoneal tissue and mesentery if death occurs during the late oliguric phase these tissues are usually dry Microscopic changes other than those concerned with the lesions observed grossly are rather meager and consist of scattered small focal areas of necrosis and hemorrhage in visceral organs Inflammatory lesions of the small vessels are conspicuously lacking but intense capillary congestion is characteristic Indeed many of the areas which appear hemorrhagic at autopsy such as the renal pyramids actually represent sites where the capillaries are extremely dilated

Differential Diagnosis During the first few days of illness the disease may be confused with leptospirosis the typhus fevers hemorrhagic smallpox idiopathic thrombocytopenic purpura leukemia or even influenza A history of exposure in the endemic area—particularly during a seasonal epidemic—and the appearance of marked proteinuria on the fourth day and the subsequent progression of the illness through the typical hypotensive oliguric and diuretic stages eliminate other diseases and warrant the diagnosis "hemorrhagic fever confirmed

Treatment and Prevention The treatment of hemorrhagic fever is limited at present to supportive measures none of the chemotherapeutic or antibiotic agents has proved of value Treatment begins with early diagnosis and prompt transfer to a hospital equipped to cope with a disease characterized by such extensive and varied physiologic disturbances

During the febrile phase complete bed rest mild sedation maintenance of reasonably normal water balance (overhydration is to be avoided) and an adequate but light diet are essential The majority of patients in the hypotensive and oliguric phases do well on a continuation of the same regimen but the severely ill require constant attention and often markedly different therapeutic measures within short periods of time Shock may develop rapidly and require prompt and active measures

Once diuresis is established special attention must be paid to adequate intake of fluid and electrolytes since 3 to 6 liters of urine may be excreted daily The principal therapeutic measure during convalescence is concerned with exercise the amount is increased *pari passu* with the recovery of concentrating capacity of the kidney

Preventive measures against hemorrhagic fever are based on avoidance of trombiculid mites which are assumed to be the vectors of the disease These measures are concerned with (1) the use of insect repellents for impregnation of clothes (benzyl benzoate) and application to exposed skin surfaces (dimethyl phthalate) (2) clearing of all vegetation from camp sites (bulldozing) and treatment of the area with residual insecticides such as lindane and (3) rodent control in and about camps by means of rodenticides

Prognosis The disease varies greatly in severity In some patients it is so mild as to make the diagnosis difficult indeed many suspected cases are not confirmed because they fail to develop the typical renal manifestations yet some of the patients with such cases undoubtedly are infected with the agent of hemorrhagic fever About 20 per cent of the diagnosed cases become critically ill The following factors contribute to the severity and influence the prognosis unfavorably delayed initiation of medical care prolonged high fever excessive fluid intake prolonged or recurrent shock persistent hemoconcentration anuria and progressive severe electrolyte disturbances The fatality rate in cases among American soldiers in Korea was between 5 and 7 per cent

diagnosis is based on the typical clinical or pathologic picture Treatment consists of supportive and corrective measures

History Etiology, and Epidemiology One particular form of hemorrhagic fever occurs in northeast Asia along the tributaries of the Amur River where it was known to the Japanese in Manchuria and the Russians in Siberia about two decades ago and in Korea where it was recognized more recently The identical disease has been described in European Russia in the Yaroslavl area of the Volga River Basin The malady is similar to but distinct from a number of other hemorrhagic fevers which exist in several parts of the Union of Soviet Socialist Republics and in Scandinavia (see the review by Gajdusek under References at the end of the chapter)

Two seasonal peaks of disease incidence are characteristic of Far Eastern hemorrhagic fever but sporadic cases are encountered during each month of the year Most of the patients are seen between mid April and early July and between early October and early December More than a thousand cases occurred annually among United Nations troops in Korea from 1951 to 1953 Thereafter the incidence decreased rapidly and only a few cases were recognized in 1956 The disease in Korea was limited essentially to military personnel stationed in rural areas north of a line drawn across the peninsula at the level of Seoul However a few civilians of all ages contracted the illness on returning to neglected farms in this area after the armistice

The majority of cases were isolated and widely spaced in regard to time place and personnel but small outbreaks did appear in military units Intensive study of such outbreaks and other observations indicated that (1) there was no person to person spread of infection (2) food and water were unimportant in the epidemiology of the disease and (3) the cases in a given outbreak acquired their infection over a period of a day or so during exposure in a sharply localized area of abandoned farm land or scrub covered terrain All these observations point to an insect vector with limited mobility and with a capacity to infect man which is effective for only short periods of time and which is ineffective during the warm and the cold months of the year

Both the Russian and the Japanese investigators who studied hemorrhagic fever in the Amur valley were able to transmit the disease to human beings by injecting them with urine or blood taken from patients during the first few days of disease Moreover each group found that the causative agent passed through filters which retained microbiologic agents larger than viruses Neither these workers nor the Americans who investigated the Korean malady were able to establish the agent in a laboratory host Recent studies on this type of hemorrhagic fever in the Yaroslavl area have given identical results i e successful experimental transmission to man but not to laboratory animals

There are many similarities between the epidemiology of hemorrhagic fever and that of scrub typhus which is transmitted by trombiculid mites (p 1036) Moreover among the various terrestrial arthropods found in the endemic areas of Korea only trombiculid mites occur in abundance during both the spring and fall outbreaks of hemorrhagic fever and are scarce when human cases are infrequent Although definitive proof is lacking it is assumed that trombiculid mites serve as the vector for the agent of hemorrhagic fever and that small wild rodents provide the reservoir for the agent

Manifestations Following an incubation period of about 2 weeks (with extremes of from 9 to 36 days) the illness usually begins abruptly with frontal headache chills high fever anorexia and backache Physical findings during the first few days of fever and prostration are essentially limited to cutaneous flush especially about the face and neck and injection of the conjunctivas About the third day petechiae generally appear on the soft palate and in the conjunctivas the axillary folds and cutaneous areas subjected to mild trauma Increased capillary permeability becomes evident about the fourth day with the appearance of pathognomonic severe proteinuria and edema of loose tissue edema of conjunctivas and periorbital tissue is visible on physical examination Edema in the lumbar gutters and mesentery contributes to the abdominal and back pain but it can be seen only at autopsy

Fever disappears about the fifth day but even in the moderately affected patient the disease continues progressing through a series of phases i e hypotensive oliguric diuretic and convalescent Manifestations of capillary leakage among them a rising hematocrit increase during the hypotensive phase but begin to abate after several days when the oliguric phase is ushered in with its associated mounting blood urea and creatinine levels With the beginning of diuresis on about the tenth day symptoms and abnormal physiologic findings generally disappear quickly However renal tubular function is restored slowly and normal concentrating capacity usually does not return until the fourth to sixth week after onset of the disease Body weight which may have decreased as much as 20 lb in the average individual during the acute illness is slowly restored to pre onset levels

Those patients in whom the disease takes a severe course display either hypotensive shock during the

is highly effective Inclusion conjunctivitis of the newborn should not be confused with gonococcal ophthalmia which invariably begins 24 to 72 hr after birth

EPIDEMIC KERATOCONJUNCTIVITIS
(Shipyard Conjunctivitis)

This is an acute infectious disease of the conjunctiva and cornea An etiologic agent has recently been identified by Jawetz and coworkers as a member of the adenovirus group type 8 (see p 1041) Epidemic keratoconjunctivitis in the United States occurs mainly in localized outbreaks in factories shipyards and eye clinics The mode of transmission is unknown but the incidence of secondary cases in family contacts is low The incubation period varies from 5 to 10 days The disease begins unilaterally with mild or severe conjunctivitis that tends to be follicular in type and is sometimes associated with pseudomembrane formation iritis and subconjunctival hemorrhages Transient fever headache and malaise are the only systemic manifestations The preauricular lymph node is usually enlarged on the affected side Within a few days the cornea becomes inflamed with resultant pain lacrimation photophobia and blurred vision The other eye is involved several days after the first in about half the cases Subepithelial corneal opacities without ulceration appear 1 to 3 weeks after onset and can persist for years resulting in impairment of visual acuity Specific chemotherapy is not available but local hydrocortisone may suppress the inflammatory reaction Epidemics can be limited by restricting contact with known cases Infections that must be differentiated from epidemic keratoconjunctivitis include Newcastle disease herpes simplex (p 1091) leptospirosis (p 1017) and cat scratch disease (p 1098)

NEWCASTLE DISEASE

This is a common and economically important disease of poultry caused by a virus of the myxovirus (influenza) group The infection in birds may be acute or chronic and is characterized by severe manifestations of respiratory gastrointestinal, and central nervous system involvement. Human infection occurs mainly in poultry workers and virologists In man accidental introduction of contaminated material into the eye is followed in 24 to 72 hr by conjunctivitis edema of the lids and profuse lacrimation The cornea is not involved and photophobia is uncommon Constitutional symptoms are absent or mild The preauricular lymph node on the affected side is swollen and tender in about half the cases Recovery is complete in 10 to 14 days and no permanent damage results The diagnosis can be suspected from the patient s occupation and confirmed by isolation of the virus in embryonated eggs The antibody response to conjunctival infection is weak and serologic tests are generally unsatisfactory No treatment is available or required

WARTS (Verrucae)

Warts are specific infectious lesions of the skin and mucous membranes caused by a virus or group of viruses The disease has been transmitted to volunteers by cutaneous inoculation of ground suspensions of warts Virus particles and inclusion bodies can be seen in histologic sections examined under the electron microscope The disease is only mildly contagious but minor epidemics have been reported Individual susceptibility seems to vary considerably with age and trauma The lesions are classified clinically by their appearance and location *Flat warts* are small round lesions usually found on the back of the hands and on the face of children *Filiform warts* occur mostly on the face and lips of adults and have numerous small fingerlike projections The *common wart* (*verruca vulgaris*) usually appears on the hands or under the fingernails as multiple raised papules with rough horny surfaces *Plantar* and *palmar warts* are deep painful flat lesions of the soles and palms covered by a thick layer of cornified epithelium *Condylomata acuminata* (moist warts) occur on the external genitalia and perineal region of young adult women and men after sexual intercourse or other contact They appear as multiple grapelike clusters that are easily differentiated from the flat condylomata lata of secondary syphilis

All forms tend to recur after removal Various methods of eradication have been employed including surgery electrodesiccation x ray freezing with solid carbon dioxide and application of caustic chemicals such as phenol, salicylic acid or silver nitrate Local application of podophyllum resin has been effective for condylomata acuminata

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is a benign infectious disease of the skin caused by a virus of the pox group The natural mode of transmission is unknown but the disease has been produced in man by cutaneous inoculation of molluscum particles Individual lesions begin as tiny papules which gradually enlarge over a period of months to a size of 1 cm or greater The fully formed lesion is a round pink waxy nodule with a centrally depressed crown. Older lesions becomes pedunculated and

192 VIRAL INFECTIONS OF THE EYE, SKIN, AND MUCOUS MEMBRANES

Robert R Wagner

The diseases described in this chapter are caused by viruses which characteristically produce localized infections in human beings They are transmitted by *direct contact or fomites* and have a low degree of contagiousness for man Although these infections are mainly of concern to ophthalmologists and dermatologists they sometimes enter into the differential diagnosis of systemic disorders that can involve the eye skin or mucous membranes A history of exposure and awareness of variations in host susceptibility will aid in their recognition Occupational contact with animals or animal products is the prime consideration in the diagnosis of Newcastle disease orf milker's nodules foot and mouth disease and vesicular stomatitis The prevalence of trachoma is largely related to poverty and overcrowding whereas epidemic keratoconjunctivitis occurs in localized outbreaks among factory and shipyard workers Age is the primary factor in susceptibility to inclusion *conjunctivitis* the several types of warts and molluscum contagiosum

TRACHOMA

Trachoma is an infection of the eye caused by a large virus related to the agents of lymphogranuloma venereum and psittacosis *Experimental* infections have been produced only in man apes and monkeys The disease is probably transmitted by fingers fomites and flies and is endemic in areas with poor sanitary conditions and low standards of living After an incubation period of *from 5 to 7* days trachoma begins insidiously or acutely with follicular conjunctivitis abundant purulent discharge swelling of the lids and enlargement of the lachrymal glands and preauricular lymph nodes This acute stage may last for several weeks before giving way to a subacute phase characterized by marked edema of the lids the formation of conjunctival blebs and progressive corneal involvement In the final stage of the disease scarring and contractures occur the lids frequently become everted and the cornea is invaded by dense fibrous tissue and blood vessels (pannus) Recurrent irritation ulceration and secondary bacterial infection commonly lead to blindness The diagnosis is most easily established in the acute stage of the disease by demonstrating typical inclusion bodies in smears of conjunctival scrapings stained with iodine or Giemsa stains Acute trachoma can be successfully treated with oral and local tetracyclines or chloramphenicol Surgery is required for removal of scar tissue in the advanced stages of the disease

INCLUSION CONJUNCTIVITIS
(Inclusion Blennorrhea)

This is an acute infectious eye disease of newborn infants children and adults It is caused by a virus similar to that of trachoma which resides in the genitourinary tract and is transmitted by sexual *intercourse* Genitourinary infection is usually asymptomatic but mild cervicitis and urethritis can occur The eyes of newborn infants are infected during passage through the birth canal ocular infection can also be contracted in swimming pools and nurseries The disease in infants is characterized by follicular conjunctivitis profuse mucopurulent exudate and pseudomembrane formation 5 to 9 days after birth The acute illness usually runs its course in several weeks but low grade conjunctivitis sometimes persists for many months Scarring and pannus formation do not occur Inclusion conjunctivitis in adults is an invariably mild afebrile infection usually confined to the palpebral conjunctiva of the lower lid Smears of conjunctival scrapings reveal inclusion bodies identical with *those of trachoma the two diseases* can be differentiated only by the clinical picture and course Oral or local treatment with tetracycline compounds

193 ENTERIC VIRUSES

Robert R Wagner and Ivan L Bennett Jr

Acute gastrointestinal disorders are second only to respiratory diseases as causes of disability Bacterial and protozoan infections account for a relatively small proportion of the total number of cases of gastroenteritis in the United States Most of the remainder are thought to be of viral etiology It is now known that a variety of viruses commonly inhabit the intestinal tract of man Poliomyelitis (p 1068) and Coxsackie A and B viruses (pp 1089 1091) are frequently present in feces of healthy individuals systemic diseases are relatively rare consequences of infection with these organisms The tissue culture techniques devised for detecting poliomyelitis viruses have resulted in the isolation of a great number of intestinal saprophytes known collectively as orphans" or ECHO (enteric cytopathogenic human orphan) viruses Types 6 and 9 ECHO viruses have been implicated as causes of benign aseptic meningitis but in general these organisms appear to live symbiotically in the intestinal tract and are rarely pathogenic It is likely that similar host parasite relationships exist for the viruses of infectious hepatitis (p 1486) Boston exanthem (p 1063) and erythema infectiosum (p 1063) but the incidence of asymptomatic carriers of these agents is not known The frequency with which the known enteric viruses produce symptoms of gastroenteritis without systemic illness has not yet been determined However during epidemics of poliomyelitis Coxsackie infections and infectious hepatitis diarrhea can be the sole manifestation of infection particularly in young children There is evidence that ECHO viruses may be responsible for outbreaks of acute febrile diarrhea in children and adults

Conventional laboratory methods used in virus research have failed to disclose the etiology of most epidemics of acute nonbacterial gastroenteritis Reports that epidemic diarrhea of newborn infants can be transmitted by stool filtrates to young calves await confirmation It is now known that most outbreaks of diarrhea in newborn nurseries are caused by certain strains of *Escherichia coli* The evidence that gastroenteritis can be produced in volunteers by inhalation of pharyngeal washings or stool suspensions is not entirely convincing However gastrointestinal symptoms may be prominent in common respiratory diseases and an epidemic of type 3 adenovirus infection (p 1041) in Sweden was associated with a 40 per cent incidence of diarrhea Many outbreaks of gastroenteritis occur in families and institutions at a time when respiratory diseases are conspicuously absent

Despite the uncertain status of the nonbacterial gastroenteritides Gordon and his associates have shown that two agents presumably viruses can be transmitted to volunteers by the oral but not by the respiratory route Immunity to one agent persisted for at least 15 months in individuals who were fully susceptible to the other Although the clinical and epidemiologic features of these two forms of gastroenteritis overlap considerably it is convenient to classify them as *afebrile* and *febrile* types (Jordan Gordon and Dorrance 1953)

Afebrile Nonbacterial Gastroenteritis ("Viral" Dysentery) The incubation period is usually 2 to 3 days but varies from 1 to 5 days The onset is often abrupt but may be gradual and preceded by malaise anorexia and nausea which almost invariably persist throughout the illness Vomiting can occur on the first day but is not prominent thereafter Crampy abdominal pains of mild or moderate severity may be the first symptom The most characteristic feature is persistent watery diarrhea without blood mucus or pus in the stools Tenesmus is uncommon although many patients have more than 20 bowel movements a day Mild headache and fever up to 101 F a day or two after onset of gastrointestinal symptoms are sometimes present The usual duration of illness is 3 to 4 days but may be as long as a week

Adults recover uneventfully without complications or sequelae Young children can become

inflamed but rarely cause pain or discomfort The papules are usually multiple and occur on any portion of the skin except the palms and soles The only treatment is surgical removal local recurrence is less frequent than is the case with warts

ORF (Ecthyma Infectiosum)

Orf is a viral disease of sheep and goats which takes the form of a benign but lingering infection of the mouth and lips The disease in man usually occurs in herdsmen who contract the infection while force feeding sick lambs Lesions appear on the hands or other exposed areas and consist of papules which rapidly vesiculate and enlarge into hemorrhagic bullae Itching is frequently intense the lesions soon rupture and become encrusted and umbilicated Mild regional lymphadenopathy is usually present but systemic manifestations are rare The lesions subside spontaneously within 2 to 3 weeks unless secondarily infected with bacteria Scarring does not occur and a single attack confers permanent immunity The only diagnostic test is isolation of the virus by inoculation of vesicular fluid into susceptible sheep The appearance of the lesions and a history of contact with lambs should suggest the correct diagnosis but orf is often confused with anthrax sporotrichosis tularemia milker s nodules inoculation tuberculosis and various forms of contact dermatitis

MILKER S NODULES

This is a benign infectious disease of dairy farmers contracted from infected cows It is presumed to be of viral etiology although the agent has not thus far been transmitted experimentally The disease in dairy cattle is world wide and is characterized by indolent ulcers and granulomas of the udder In man lesions appear 5 to 7 days after milking an infected cow they occur mainly on the hands but are occasionally seen on other exposed areas The lesions are often multiple and begin as dark papules which gradually enlarge into firm brownish red or purple nodules from 1 to 2 cm in diameter They are rarely painful or tender and contain no fluid or pus A gray depressed eschar gradually forms on the surface of a red base of granulation tissue and the lesions heal slowly after several weeks leaving no scar The lymph nodes draining the site of infection may enlarge but there are no other local or systemic manifestations Milker s nodules are often confused with cowpox which is caused by an entirely different virus (see p 1062) No specific treatment is available or required

FOOT AND MOUTH DISEASE

This is a highly contagious disease of cattle and other domestic animals caused by the smallest virus known to infect animals or man In the United States rigid quarantine and slaughter of infected animals have confined the disease to a few outbreaks near the Mexican border The rare instances of human infection have resulted from ingestion of meat or dairy products or from exposure to excreta hides or entrails of sick animals In man the illness starts abruptly with fever malaise and headache after an incubation period of 2 to 18 days Initially there is extreme dryness of the mouth followed shortly by excessive salivation and generalized pruritus After several days large clear vesicles appear in the mouth and pharynx and over the palms and soles Rarely the skin is affected elsewhere The lesions of the mucous membranes and skin are painful and soon become shallow ulcers that bleed easily The ulcers heal spontaneously within 2 to 3 weeks leaving no scars The virus can be isolated in guinea pigs by inoculation into the footpad of fluid from the vesicles A complement fixation test is also available for detecting specific serum antibodies in convalescence

VESICULAR STOMATITIS

Vesicular stomatitis is a contagious disease of horses mules cattle and swine Human infection occurs rarely in veterinarians farmers and virologists after an incubation period of 24 to 48 hr In man the disease is characterized by sudden onset with shaking chills high fever headache and prostration The fever and symptoms subside completely after 24 to 48 hr but the same symptoms may recur 3 to 4 days later This second phase of the disease usually lasts a week and is accompanied by the appearance of papular and vesicular lesions in the oropharynx that form superficial ulcers The cervical lymph nodes are often swollen and tender The diagnosis can be confirmed by virus isolation or serologic studies

feces unchanged or may develop into precysts which in turn develop into mature cysts on meeting conditions outside of the host unfavorable for the parasite

Pathogenesis The trophozoites invade the mucosa extend through the muscularis into the submucosa and produce small flask shaped ulcers which contain yellowish brown necrotic material Elaboration of cytolytic enzymes and perhaps of *hyaluronidase probably aids in this tissue destruction* There is little or no cellular reaction around the ulcers unless they are secondarily infected by intestinal bacteria The entire colon is often involved in the process The cecum ascending colon rectum sigmoid and appendix are involved in that order The inability to produce amebiasis by inoculation of *E histolytica* into animals reared in a germ free environment suggests that symbiosis with normal intestinal bacteria is a *sine qua non* for actual disease production

A delicate host parasite relationship determines whether or not symptoms occur In an early experiment 20 volunteers were fed cysts of *E histolytica* Eighteen became parasitized and passed amebas in the stools Of the entire group however only 4 developed dysenteric symptoms It has been estimated that nearly 90 per cent of persons infested do not have striking symptoms In these the size of the ulcers remains microscopic Small ulcers may coalesce however to form larger ones resulting in any of the diarrheal symptom complexes Amebas which have invaded the colonic mucosa may have any of the following fates (1) They may be completely eradicated (2) maintain an asymptomatic carrier state by virtue of the minute ulcers (3) produce larger ulcers which are symptomatic (4) pass through radicles of the portal veins lodge in the liver and produce hepatitis and/or abscess formation (5) travel via the blood stream or by direct extension to other locations inducing less common disease entities

Epidemiology Amebiasis is world wide in distribution with the highest incidence of the disease in tropical and subtropical regions It is more prevalent in the southern than in the northern parts of the United States It has been estimated that the over all infestation rate in the United States is in the neighborhood of 10 per cent but the true incidence in various locales has not been determined The Chicago epidemic of 1933 attributable to a defective plumbing system in one of the larger hotels attests to the fact that urban areas are by no means immune Servicemen returning from Second World War service in endemic areas and those recently back from Korea are a further potential source of amebiasis However a survey conducted in a Veterans Hospital in the southeastern United States in 1951 revealed a rate of 10 per cent infested with cysts—not in excess of that expected in the population unexposed to endemic areas of infestation

Amebiasis is transmitted from man to man there are no intermediate hosts In areas with good sanitation the principal source of infection is the food handler who passes cysts in his excreta In more primitive areas where human fecal material is used for fertilization of the soil vegetables improperly cooked are a large factor in perpetuating amebiasis Since the trophozoites die rapidly upon exposure to changes in temperature active cases of amebic dysentery are not a menace Upon convalescence and with the beginning of passage of cysts which are much more resistant to external environs these persons then join with the chronic cyst carriers as potential spreaders of the disease Contaminated water supplies and flies may spread the infection

Modes of prevention are concerned with improvement of sanitation with recognition of carriers and their removal from food handling and with education of the general public as to the potential dangers of amebiasis so that milder degrees of amebiasis can be recognized treated and the carrier state prevented

Clinical Features *Dysentery* As mentioned previously the majority of persons infected by *E histolytica* are asymptomatic The commonest clinical syndromes noted are varying degrees of diarrhea

In the usual case amebic dysentery is insidious in onset Vague lower abdominal cramping sensations with one or more loose stools a day are often the first symptoms noted The stools are usually foul smelling and often contain bits of bright red blood and some mucus Vague indigestion a sense of being unwell a low grade fever and alternating periods of constipation and diarrhea are often accompanying symptoms It is not unusual to find that such symptoms have been present intermittently for months or even years before a definite diagnosis is made There is little to note on physical examination except for slight tenderness along the course of the colon and some evidence of weight loss

Acute Amebic Dysentery A less commonly observed variant is acute amebic dysentery Patients so affected have a sudden onset of acute bloody dysentery with frequent stools tenesmus severe abdominal pain and at times vomiting The temperature is elevated at times as high as 105 F During combat conditions of the Second World War it was noted that this picture frequently accompanied acute bacillary dysentery It is possible that in such a situation the bacterial infection activates acute amebiasis in a person who otherwise is a relatively asymptomatic carrier

Asymptomatic Cases In the so called *asymptomatic cyst passer* it is often found on careful an

severely dehydrated requiring parenteral replacement of fluid and electrolyte losses Symptomatic relief of diarrhea is best achieved with tincture of opium (paregoric) given after every bowel movement or every few hours

Febrile Nonbacterial Gastroenteritis The incubation period is 20 to 30 hr The onset is usually abrupt and characterized by moderately severe colic abdominal pain and vomiting Diarrhea is infrequent although there may be an increased number of formed or soft stools Chilliness and cold sweats may be present at the onset and fever of 101 to 103 F headache malaise and prostration are prominent features The illness rarely lasts longer than 48 hr Specific treatment is not available but atropine may relieve the abdominal pain and vomiting

A disorder known as winter vomiting disease appears to be similar in onset duration and clinical manifestations but is more frequently associated with diarrhea It is only mildly contagious and has not been transmitted to volunteers

Laboratory Findings No specific diagnostic procedures are available but stool examination and cultures are helpful in excluding more serious gastroenteritides

Differential Diagnosis Dietary indiscretions excessive ingestion of alcohol and psychologic stress can precipitate vomiting and diarrhea that closely simulate acute gastroenteritis Staphylococcal food poisoning (p 843) invariably has a precipitous onset of severe vomiting and retching ordinarily without fever or diarrhea 1 to 6 hr after ingestion of the incriminated food Salmonella gastroenteritis (p 889) usually has a 12 to 24 hr incubation period and is often associated with systemic manifestations fever and leukocytosis Outbreaks of food poisoning are characterized by explosive and simultaneous occurrence of symptoms in affected individuals without late secondary cases whereas epidemics of viral gastroenteritis begin insidiously usually continue for several weeks and cannot be traced to food or water supplies Mild shigellosis (p 891) may be difficult to differentiate from "viral" gastroenteritis but outbreaks usually result in cases with sustained fever tenesmus and bloody purulent stools that contain pathogenic bacteria

Section 17 Protozoan Infections

194 AMEBIASIS

Max Michael Jr

Definition The term amebiasis denotes infestation by the protozoan *Endamoeba histolytica* The primary effect of this parasite is on the large bowel but it may also invade the liver and lungs and less commonly the ileum skin brain and pericardium

Etiology *Endamoeba histolytica* infests the intestinal tract of man and of some species of monkeys rats cats dogs and swine A large race of high virulence and a small less virulent race have been described Present evidence however does not indicate that any of the races lack human pathogenicity *Two forms* are recognized the motile (vegetative) or trophozoite and the encysted or cyst When infective cysts are ingested by the host they pass through the stomach unchanged but upon reaching the lower small bowel find conditions that are favorable for excystment Division then occurs each cyst ultimately yielding eight new trophozoites capable of invading the colonic mucosa In the wall of the intestinal tract reproduction takes place by binary fission with liberation of trophozoites These may then invade the host tissue or may pass in the

tially but do not prevent clinical relapse or the carrier state from ensuing It is often necessary to follow one agent with a course of another to effect a real cure Present evidence indicates that best results will be obtained by a course of oxytetracycline (2 Gm a day for 10 days) or a combination of Milibis and chloroquine diphosphate (0 5 Gm Milibis and 0 15 Gm chloroquine diphosphate each t i d for 7 days) An older but still satisfactory regimen consists of carbarsone (0 25 Gm t i d for 10 days) followed by chiniofon (1 0 Gm t i d for 10 days) Emetine which enjoyed wide popularity for many years is now reserved for some cases of extraintestinal amebiasis It is a toxic drug and may produce myocarditis or peripheral neuritis

In the majority of cases diarrhea ceases and symptomatic improvement is striking after the first 2 or 3 days of therapy Lack of symptoms does not constitute cure and the goal of therapy is complete eradication of amebas from the body Careful follow up studies of stool concentrates for at least 6 months are desirable If clinical relapse occurs or cysts reappear re treatment is indicated Whenever liver involvement with the parasite is suspected chloroquine which is effective against amebas in this organ but not against those in the bowel (see below) should be added to the therapy liver abscesses have enlarged and become symptomatic while the patient was receiving drugs effective in the bowel alone (e g oxytetracycline) Treatment of the asymptomatic carrier is the same as for the person with active dysentery The cyst passer must not handle food for others until the stool has become free of parasites

The amebicides are not without toxicity Chiniofon as well as the antibiotics may cause diarrhea which can make evaluation of symptom response rather difficult The toxicity of emetine has been mentioned The iodides may occasionally cause rash and fever and the arsenicals may rarely produce exfoliative dermatitis or liver damage

Hepatic Involvement At any time in the course of infestation of the colon amebas may be carried to the liver In many instances they are destroyed there but in approximately 5 per cent of cases of amebic dysentery disease is manifest in the liver with hepatitis or abscess No clearcut distinction between the two is warranted as they differ only in degree

The amebas gain access to the liver through the portal circulation and localize principally in the right lobe Rarely invasion occurs by way of lymphatics or by direct extension The pathology is characterized by scattered areas of necrosis and degeneration of liver parenchyma with an absence of inflammatory response unless secondarily infected In experimental amebic hepatitis thrombosis of the smaller portal vein radicles is a prominent feature With healing small fibrotic lesions which do not impair liver function result Calcification is rare

Clinical evidence of liver involvement may be apparent without bowel symptoms Only 25 per cent of patients have diarrhea at the time of the liver disease A history suggestive of amebic dysentery weeks or years in the past is obtained in about half the cases Amebas are found in the stools in somewhat less than half the cases The essential point to be remembered is that amebic liver disease can occur without any preexisting or coexisting manifest bowel disease

The clinical states that ensue vary from an acute fulminating hepatitis to a mild indolent abscess In some instances there is sudden onset with chills sweats severe abdominal pain tending to localize in the right upper quadrant nausea vomiting and spasm of abdominal muscles Fever may be as high as 104 F and the leukocyte count over 25 000 The differential count is frequently normal Any of the acute abdominal emergencies such as cholecystitis ruptured viscus and acute pancreatitis may be simulated but a few facts suggest diffuse amebic hepatitis Tenderness is marked over the liver and localized areas of tenderness may be noted Abscess formation is suggested by pain referred to the shoulder some hepatic enlargement low grade fever weight loss and tenderness over the liver A nonproductive cough may be noted Point tenderness in one of the intercostal spaces over the right lobe suggests abscess formation Jaundice and other evidences of impaired liver function are unusual (Abscess may exist with a normal white cell count) Certain roentgenologic features aid in the diagnosis of abscess formation Elevation of the right dome of the diaphragm and obliteration of the cardiophrenic angle and of the anterior costophrenic angle on lateral view are suggestive of abscess formation Aspiration of the contents of an abscess yields a thick chocolate colored material which has been likened to anchovy paste It is rare to find amebas in the pus since they are principally in the wall of the abscess

The response to treatment of amebic liver disease serves as an important diagnostic tool Chloroquine diphosphate which is highly concentrated in the liver has proved to be quite effective against amebas in this organ It is rapidly becoming the drug of choice replacing emetine which though potent is toxic The dosage is 1 0 Gm a day for 2 days followed by 0 5 Gm a day for 21 days Its effects on the bowel disease are not of a high order hence one of the agents effective for the bowel disease (e g oxytetracycline) is given concomitantly in order to attack any parasites which may be in

amnesis that vague digestive complaints and an occasional mild diarrhea have been noted by the patient The cyst carrier is more than a potential public health menace He may on occasion revert to a stage of active dysentery Furthermore any of the serious metastatic manifestations of amebiasis may develop in such asymptomatic individuals

Amebic Granulomas Amebic granulomas the so called *amebomas* which are single or multiple may be located in any region of the large bowel particularly in the cecum They usually develop in long standing cases of amebic dysentery It is important that they be recognized and differentiated from carcinoma which they may simulate Surgical intervention before antiamebic therapy is administered is attended by a high mortality

Diagnosis Amebic dysentery should be considered in every case of diarrhea The character of the stool is often of considerable aid in the diagnosis In the usual type of amebic dysentery it is soft or even loose and watery Flecks of mucus and bright blood frequently cling to the outside of the stool Microscopic examination must be performed on a fresh warm stool The cellular exudate in the feces is predominantly mononuclear in contradistinction to the polymorphonuclear exudate of bacillary dysentery *Several examinations may be necessary* to find the parasites Care in choosing flecks of bloody mucus for study is rewarding In such bits of exudate motile amebas often with ingested red blood corpuscles will be seen The amebas move actively about the stage by thrusting out pseudopodia of clear cytoplasm into which may flow red corpuscles and other particulate matter The motile forms of *E coli* a nonpathogenic inhabitant of the bowel may be confused with *E histolytica* The former are only sluggishly motile do not throw out clear pseudopodia and never contain ingested red corpuscles Motile forms not previously evident may appear in stools following a magnesium sulfate purge If parasites are not found cyst forms should be looked for in a stool concentrated with zinc sulfate and stained by appropriate methods *Endamoeba histolytica* may be cultured from stools by use of special media In the hands of qualified workers this method increases the chances of obtaining positive results and is especially efficacious for recognition of the cyst passer

The *proctoscopic examination* yields valuable information In the early stages of the disease small shallow ulcers often covered with mucous flecks will be seen Punctate hemorrhage and hyperemia may be noted The intervening mucosa usually appears normal As the disease progresses the ulcers become deeper and develop slightly raised edges giving the appearance of bomb craters They may be multiple and small or single and large Material obtained from one of the ulcers either by cotton swab or by aspiration is usually swarming with motile trophozoites Lesions will not be seen in all cases since involvement of the right side of the colon may constitute the sole lesion

The *complement fixation test* for amebiasis offers potential diagnostic and therapeutic aid However the difficulty in preparing a stable antigen has led to diverse results Many laboratories have so standardized the procedure that less than 10 per cent of patients with amebic dysentery have a positive test whereas 85 per cent of those with hepatic amebiasis have a positive test It reverts to negative upon eradication of the amebas The implications of the test are apparent A mild normocytic anemia is noted in chronic cases The white blood count is slightly elevated in mild cases and may be as high as 30 000 in the cases of the acute type

Differential Diagnosis All causes of diarrhea enter into the differential diagnosis The simple diarrheas whether caused by *Salmonella* viruses or enterotoxins or whether of functional or unknown causes may simulate the milder forms of the disease Moreover acute amebic dysentery can simulate acute bacillary dysentery in onset and in course In this respect it should be mentioned that large *mononuclear cells which appear in the fecal exu*date in bacillary dysentery may be confused with amebas Ulcerative colitis offers the chief difficulty in differential diagnosis from the usual type of amebic dysentery however its chronicity proctoscopic and radiologic appearance and lack of response to antiamebic therapy are aids in the differentiation Mucous colitis regional enteritis and carcinoma of the large bowel are other entities requiring consideration In all cases in question careful and repeated stool examinations adequate proctologic examination and response to therapy will usually establish or exclude the diagnosis of amebic dysentery

Treatment It cannot be said categorically that there is a drug of choice in the treatment of amebiasis The many drugs available can be grouped into five classes A drug from a single class is often effective whereas others are combined with agents from one or more of the other groups to achieve effects The groups with representatives of each are (1) arsenicals (carbarsone Milibis) (2) halogenated quinolines (Diodoquin chiniofon Yatren) (3) antibiotics (oxytetracycline bacitracin) (4) ipecac derivatives (emetine) and (5) aminoquinolines (chloroquine) The ideal therapy terminates the acute attack promptly eradicates parasites from the bowel wall and thus prevents the chance of further relapse of the patient or of a menacing carrier state Many drugs fall short on the last two items They eradicate the amebas in

Man is the intermediate host and the mosquito the definitive host In man after a stage of exo-erythrocytic development the parasites reproduce asexually in circulating erythrocytes They first appear in the red cells as *ring forms* after several divisions daughter cells (*merozoites*) fill the corpuscle which ruptures and releases them to parasitize additional erythrocytes With repetition of this cycle some of the red cells become filled with sexual forms (*gametocytes*) these do not induce cell lysis and are unable to undergo further development unless ingested by an appropriate mosquito during a blood meal In the stomach of the mosquito fertilization occurs and the resulting *ookinete* encysts on the outer surface of the stomach and releases myriads of *sporozoites* These migrate to the salivary glands and if inoculated into a human subject lead to repetition of asexual multiplication There is variation in this cycle among different species and several intermediate developmental stages occur

The asexual cycle in the erythrocyte requires 36 to 48 hr for *P falciparum* 48 hr for *P vivax* and *P ovale* and 72 hr for *P malariae* The periodicity of febrile paroxysms in infections by the different species coincides with the cyclic discharge of merozoites and infestation of new cells

The incubation period between bite of an infected mosquito and onset of symptoms is 10 to 14 days in vivax and falciparum malaria and 18 days to 6 weeks in quartan infections

There is good evidence for the existence of several strains of each species of human malarial *Plasmodium* and greater virulence of some strains is suggested by the consistent severity of the clinical illnesses which they produce

Epidemiology Malaria survives only in areas where the mosquito and the infected human populations remain above a *critical density* for each These critical densities are interdependent but either may fluctuate in a given area Control measures are directed toward reducing both populations to levels that are too low for the infection to survive Important procedures include drainage or filling of breeding areas use of residual insecticide sprays (this has largely replaced the use of oil or other antilarval measures) screening use of skin repellents effective treatment of cases and large scale suppressive drug programs in some human populations

The disease remains highly prevalent in many parts of the world and it is estimated that more than two hundred million cases occur annually An active international cooperative program of malaria control has resulted in a significant decline in the incidence of the disease since 1945 and despite the enormity of the remaining problem many areas in South America southern Europe and Asia are now almost free of the infection

Manifestations *General* There is some variation in the clinical diseases produced by the different plasmodia but in all chills fever excruciating headache muscle pains splenomegaly and anemia are common Herpes labialis is very frequent but usually appears only after the infection is well established Hepatomegaly and mild icterus are often observed especially in estivo autumnal infections

The hallmark of the disease is the malarial *paroxysm* which recurs at regular intervals in all but falciparum infections The typical paroxysm begins with a rigor that lasts 20 to 60 min ("cold stage) followed by a "hot stage" of 3 to 8 hr with fever of 104 to 107 F The "wet stage" consists of defervescence with profuse diaphoresis which leaves the patient weak and exhausted

First attacks of malaria are often severe but with repeated episodes symptoms become milder although debilitation may be progressive There is good evidence for the development of immunity to malaria but it is of a low order in so far as protection against reinfection is concerned Negroes are peculiarly insusceptible to *P vivax* infections

Tertian Malaria (P Vivax or P Ovale) This infection is rarely fatal although relapses are common and it is the most difficult to cure A prodrome of myalgia headache chilliness and low grade fever for 48 to 72 hr heralds the onset of the typical paroxysms Transient urticaria sometimes precedes each of the paroxysms which occur on alternate days unless there has been double infection with two maturation cycles in which case daily chills can occur Such double infections usually synchronize" within a week and paroxysms then follow the classic tertian pattern

Quartan Malaria (P Malariae) In this infection paroxysms occur every third day unless multiple infection alters the cycle initially and chills occur on 2 out of 3 days or even daily until the cycles synchronize Quartan malaria is usually a more disabling infection than tertian but responds well to treatment Edema albuminuria and hematuria (not hemoglobinuria) a clinical state similar to acute hemorrhagic nephritis occasionally appear during the course This complication should not be confused with *blackwater fever*

Estivo Autumnal Malaria (P Falciparum) This is a severe disease The organisms are present in enormous numbers and there is a striking tendency for agglutinated masses of parasitized erythrocytes to block capillaries throughout the body producing localizing signs that mimic many other diseases There is often "asynchronization" of the cycle of multiplication typical malarial paroxysms occur

this location Within 3 to 5 days of commencing therapy dramatic changes are usually noted The temperature returns to normal leukocytosis subsides pain and tenderness decrease remarkably the liver size decreases and a sense of well being returns In those cases with persisting abscess formation as evidenced by continuing localized tenderness or an abnormal bulge in the diaphragm the contents must be evacuated while chloroquine therapy is continued The aspiration is performed with an 18 gauge needle at the point of maximum tenderness over the liver One aspiration usually suffices but continuing pain and localizing signs are indications for another attempt At times it is difficult to decide whether to aspirate since the presence of abscess cannot be definitely established however it is a good general rule to aspirate when in doubt In view of its faster acting properties emetine should be given to the gravely ill patient or to the patient whose abscess has been entered surgically It should also be used when the abscess has not responded to chloroquine therapy Emetine hydrochloride is administered subcutaneously in doses of 0 065 Gm daily for 7 to 10 days If the abscess is infected secondarily with pyogenic bacteria appropriate antibacterial chemotherapy should be instituted

If abscesses are not treated properly the patient may become cachectic and die of infection On the other hand the abscess may rupture into the lungs producing any of the pulmonary syndromes

Pleuropulmonary Involvement Direct extension into the pulmonary tract occurs in approximately 15 per cent of cases of amebic liver disease The right lung and pleural cavity are the areas involved Rarely the lesions may be metastatic without any detectable evidence of preexisting liver disease When the process of extension is a gradual one and the pleural surfaces have adhered to each other the abscess penetrates either directly into the lung causing an abscess or directly into a large bronchus producing a hepatic bronchial fistula If the process is more acute extension into the pleural cavity with empyema results These three conditions occur with about equal frequency

The signs and symptoms of pleuropulmonary amebiasis are similar to those of suppurative disease in these areas In some cases the first indication of the amebic nature of the disease is the expectoration of copious amounts of a dark chocolate brown pus which may taste like liver As indicated most of the patients have accompanying liver involvement and in them pulmonary invasion is manifested by cough septic fever and localized chest pain Roentgenologic demonstration of elevation of the right dome of the diaphragm with overlying pulmonary infiltration is highly suggestive of amebiasis In the lateral view a triangular area of pulmonary infiltration overlying a bulging diaphragm is helpful in diagnosis

Management of pleuropulmonary amebiasis is similar to that for amebic liver abscess Frequent bronchoscopic drainage may be indicated for localized lung abscesses With secondary infection antibacterial chemotherapy should be instituted

Other Manifestations *Endamoeba histolytica* may involve any region of the body Other rarer manifestations include pericarditis resulting from direct extension from the liver peritonitis secondary to rupture of liver abscess urethritis vaginitis and brain abscesses which are metastatic Cutaneous lesions resulting from draining sinuses infected with amebas are exceedingly painful and destructive Their response to therapy is satisfactory Otherwise unexplained generalized urticaria results from parasitism by amebic cysts in a small number of cases The urticaria abates upon eradication of the amebas

195 MALARIA

Ivan L Bennett Jr

Definition Malaria is a protozoan disease transmitted to man by the bite of *Anopheles* mosquitoes Although it is now rare in the United States it is probably the most prevalent infectious disease throughout the world Malaria is characterized by rigors fever splenomegaly anemia and a chronic relapsing course

Etiology The causative organisms are protozoa of the genus *Plasmodium* The four species known to infect man do not produce disease in lower animals although many other species affecting animals and birds are known *Plasmodium vivax* causes tertian malaria *P malariae* causes quartan malaria *P falciparum* causes malignant tertian (estivo autumnal) malaria *P ovale* causes ovale tertain malaria a relatively rare and mild illness

narcotics) should suggest the disease Splenomegaly is an almost invariable finding its absence is strong evidence against malaria Leukocytosis is not a feature of malaria

The confusion of *P falciparum* malaria with various disorders of the brain lung or intestine has been mentioned

While final cure of malaria may be difficult particularly in *P vivax* infections almost all cases will respond symptomatically to quinine or one of the newer antimalarial drugs and failure of response to a therapeutic trial argues strongly against the diagnosis

Treatment The use of appropriate chemotherapy can suppress symptoms in individuals exposed in endemic areas or cure malarial infection completely The development of new antimalarial drugs has led to replacement of quinine and Atabrine (quinacrine) as the agents of choice although both will undoubtedly continue to be used for many years A good dosage schedule for quinine sulfate is 1 0 Gm orally t i d for 2 days and 0 6 Gm daily for 1 week Quinine dihydrochloride can be given intravenously (not intramuscularly) in a dose of 10 ml of a 3 per cent solution every 4 hr until oral medication can be taken

The oral dosage of Atabrine is 0 2 Gm every 6 hr for five doses and 0 1 Gm t i d for 6 days Quinacrine dihydrochloride can be given intramuscularly (*not* intravenously) in a dose of 0 2 Gm every 6 hr until oral therapy can be tolerated

The initial administration of 600 mg chloroquine (Aralen) base followed by 300 mg 6 hr later and then 300 mg daily for 2 days usually produces complete subsidence of *P falciparum* and *P ovale* infections For *P vivax* and *P malariae* infections another drug should be combined with chloroquine to avoid relapse common in both types Fifteen mg primaquine base by mouth daily for 14 days is the best regimen relapse after treatment by this combination is extremely rare

The suppressive dose of chloroquine is 300 mg once weekly General supportive measures fluids good diet symptomatic relief of headache or other pains and occasionally blood transfusions are all important

Specific antimalarial drugs should be withdrawn in patients with blackwater fever

Overdosage of quinine produces cinchonism with tinnitus as an early manifestation Occasional instances of mild hemolysis attributable to it have occurred and it is a cause of allergic purpura (non thrombocytopenic) and drug fever

Atabrine causes a yellow staining of the skin Given intravenously it usually produces circulatory collapse Primaquine produces hemolytic anemia in many Negroes apparently because of an inborn error of erythrocyte metabolic activity (see p 1164) Chloroquine rarely causes any reaction other than occasional mild desquamation and itching

196 LEISHMANIASIS

Edward S Miller

Definition and Etiology Protozoa of the genus *Leishmania* cause several different diseases which are referred to collectively as leishmaniasis *Visceral leishmaniasis* is a generalized systemic infection commonly referred to as *kala azar* caused by *Leishmania donovani* Two types of *cutaneous leishmaniasis* are generally recognized *oriental sore* is due to *L tropica* *American cutaneous* or *mucocutaneous leishmaniasis* is caused by *L braziliensis*

In vertebrate hosts the parasites lie within reticuloendothelial cells and take the form of nonflagellated oval organisms (Leishman Donovan bodies) 2 to 3 μ in diameter In the body of the sandfly they become flagellated The several members of this genus are indistinguishable morphologically and culturally but they differ antigenically and the diseases to which they give rise are distinctive Persons recovering from kala azar or oriental sore possess a considerable degree of homologous immunity On the other hand the two diseases do not immunize against each other

Epidemiology and Pathogenesis Leishmaniasis is transmitted by various species of biting sandfly (*Phlebotomus*) vectors which become parasitized by sucking the blood of infected hosts and which subsequently transmit the infection by regurgitating into the bite wounds of succeeding victims These diseases are endemic only in tropical and semitropical regions where sandflies are found The flies feed chiefly at night and are found mostly in rural areas Organisms are present in the open lesions in oriental sore and in American leishmaniasis and these diseases can also be transmitted by contact

but continuous remittent or irregular fever is present in many cases and illness can be constant

The course of uncomplicated estivo autumnal malaria is ordinarily milder than that of tertian or quartan infections However capillary blockage by the parasites can give rise to serious even fatal complications and it is this feature of *P falciparum* infections that accounts for the protean manifestations of estivo autumnal malaria and the relatively high morbidity and mortality associated with it Depending upon the organ system involved several so called *pernicious syndromes* are seen *Cerebral malaria* can lead to hemiplegia convulsions delirium hyperpyrexia coma and rapid death When the *pulmonary* circulation is involved there may be cough and blood streaked sputum leading to confusion with many other diseases of the lung The splanchnic capillaries can be obstructed with consequent vomiting abdominal pain simulating appendicitis severe diarrhea or melena Such patients are sometimes thought to have bacillary dysentery or cholera Fever in these disorders may be low or absent Indeed in patients with predominantly gastrointestinal manifestations there are usually cold clammy skin hypotension profound weakness and repeated syncopal attacks so called *algid malaria*

Blackwater Fever This is a disorder that occurs in association with malaria particularly and perhaps only with *P falciparum* infections The usual attack begins with a rigor and fever followed by massive intravascular hemolysis icterus hemoglobinuria collapse and often acute renal failure and uremia The pathologic findings in the kidney are typical of lower nephron nephrosis with necrosis of tubules and hemoglobin casts The mortality is 20 to 30 per cent and survivors are very likely to experience hemolytic episodes with subsequent malarial infections

Although blackwater fever is often classified as one of the pernicious complications of estivo autumnal malaria its etiology is obscure There is nothing to suggest that capillary blockage by the parasites produces the renal disturbance *P falciparum* has not been shown to elaborate a hemolysin and in many patients with blackwater fever parasitemia is absent Conflicting evidence suggests a possible role of therapy with quinine in the hemolysis there are good observations to the effect that antimalarial drugs in general neither speed recovery from an attack nor influence the outcome Tender splenomegaly is a constant finding and this has led to the suggestion that the hemolysis is a result of hypersplenism In the past cardiac decompensation has been the usual cause of death in patients with blackwater fever It is probable that the heart failure resulted from overhydration in ill advised attempts to flush the kidneys of oliguric patients The institution of an appropriate regimen for acute renal failure (see p 1367) should reduce the fatality rate considerably

Complications In addition to the several complications already mentioned others deserve comment Rupture of the spleen is relatively rare but malaria is by far the commonest cause of spontaneous rupture and predisposes to traumatic rupture of this organ

Chronic malaria or repeated infection in an endemic area leads to anemia debility and cachexia Secondary bacterial infection is often the immediate cause of death in such patients Bacillary dysentery cholera and pyogenic pneumonia are common Tuberculous foci often extend in malarial patients and miliary tuberculosis is occasionally observed

Laboratory Findings The blood leukocyte count is usually low but may be normal The erythrocyte sedimentation rate is elevated Plasmodia are demonstrable in smears of peripheral blood from the vast majority of patients with symptomatic malaria When the disease is suspected appropriately stained blood films should be examined diligently For the inexperienced examiner a thin smear of fingertip blood on a clean glass slide should be stained with Wright Giemsa or Hastings stain Parasitized erythrocytes are most frequent at the edges of a smear extracellular parasites are not found Thick smears should be thoroughly dried and stained with diluted Giemsa or Field stain This method has the advantage of concentrating the parasites but artefacts are numerous and correct interpretation of these preparations requires much experience

The morphology of the four species of plasmodia that infect man is specific enough to allow identification in blood smears The details of this morphology are available in textbooks of parasitology The parasitized erythrocytes in *P vivax* infections are usually enlarged and hypochromic in *P malariae* infections they are small and hyperchromic and in *P ovale* infections the red cells containing parasites are oval

There is no advantage over blood of material obtained by splenic or sternal puncture The administration of epinephrine with the idea of dislodging parasites by producing contraction of the spleen has been advocated but results are irregular There are no reliable diagnostic serological tests

Diagnosis The most important diagnostic test is the search for parasites in peripheral blood History of residence in an endemic area previous attacks of malaria typical malarial paroxysms or some artificial exposure (blood transfusion addiction to

used systemically the trivalent compounds are more effective Tartar emetic may be given in a dose of 0 1 Gm intravenously on alternate days for a total of 12 to 15 injections

The treatment of the American form of cutaneous leishmaniasis is similar to that of oriental sore Antimonials are only moderately effective but nevertheless essential when mucous membrane lesions are present tartar emetic is the drug of choice

Definition Toxoplasmosis a disease of increasing importance results from infection with an intracellular protozoan parasite *Toxoplasma gondii* which is widely distributed among mammals and birds In man it may produce acquired or congenital illness The former is frequently unapparent

History First demonstrated in 1908 by Nicolle and Manceaux in a North African rodent the gondi and in the same year by Splendore in Brazil *Toxoplasma* was not definitely related to human disease until 1939 when Wolfe Cowen and Paige described infantile cases of encephalomyelitis which had resulted from congenital infections with the parasite Several cases of the acquired disease were reported shortly thereafter but interest in *Toxoplasma* was limited and it was considered to be important principally as the causative agent of a rare congenital di ease The disease producing capabilities of the parasite have become more evident in recent years as the result of the almost simultaneous descriptions of skin complement fixation and dye tests These have been utilized extensively enough to make it apparent that *Toxoplasma* frequently infects man and animals and that congenital

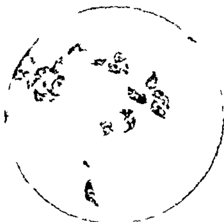

FIG 149 *Toxoplasma* in Wright stained impression film (×1200)

toxoplasmosis is only a segment of a broad relatively common disease spectrum

Etiology *Toxoplasma gondii* is considered to be a protozoon All strains regardless of source appear to be antigenically similar and of the same species The organism measures about 3 0 by 6 0 μ and may appear crescentic oval or round (see Fig 149) It divides by binary fission and is best stained with either Wright or Giemsa stain *Toxoplasma* an obligate intracellular parasite is unique in that it may infect any mammalian or avian cell except erythrocytes It can be maintained in tissue culture or embryonated eggs but does not multiply in the absence of living cells The parasite is readily sedimented by centrifugation Under special conditions it may be stored in the frozen state but ordinary freezing kills the organism

Laboratory Diagnosis A specific diagnosis may be made by the application of serologic methods by demonstrating the organism in smears or by isolating it in mice *Toxoplasma* may be seen in Wright or Giemsa stains of the sediments of spinal or ventricular fluids or occasionally in histologic sections of biopsied lymph nodes or muscle obtained during the active phase of the illness The laboratory mouse is the animal of choice for attempting isolations and may be inoculated with spinal fluid sediment (when acute central nervous system signs are present) or emulsions of fresh tissue At least three blind passages should be made with brain and spleen emulsions before considering the attempt a failure

Serum antibodies may be detected with either the dye or the complement fixation test As is true of serologic procedures in general the results are most meaningful when a rising titer is demonstrated Dye test antibodies seem to develop early and persist for many years possibly for life Complement

It is possible that kala azar occasionally may be transmitted directly from man to man also since the protozoa are sometimes found in nasal secretions pharynx urine and feces of patients Human beings serve as the major reservoir of leishmaniasis Dogs are also of importance in certain Mediterranean areas and in China and naturally infected rodents and other animals are found in other parts of the world

Manifestations *Kala-azar* This disease is prevalent in India China North Africa and countries bordering the Mediterranean A few cases have been observed in South America (Brazil Argentina Bolivia and Venezuela) The incubation period is usually from 2 to 4 months Onset may be gradual or abrupt and the clinical course evolves slowly over a period of months Irregular bouts of fever often with daily double spikes eventually are followed by loss of weight and strength hyperpigmentation of the skin painless hepatomegaly splenomegaly peripheral edema and sometimes lymphadenopathy The bone marrow is hyperplastic and its function is disturbed with reduction of the total leukocyte count to less than 4 000 per cubic millimeter agranulocytosis with its attendant complications is occasionally seen There are a moderate to severe normocytic and normochromic anemia and some diminution in the platelet count Bleeding may occur from the nose gums or intestinal tract or into the skin Liver function test results are frequently abnormal in cases of more than 3 months duration The serum albumin is decreased while the globulin content rises sharply Hyperglobulinemia can be demonstrated readily by means of the formol gel (Napier s aldehyde) and antimony tests Unless treated kala azar is fatal within 2 years in 75 to 95 per cent of cases Patients who recover sometimes develop unusual dermal lesions after a lapse of a year or more The lesions may appear anywhere on the body and are pleomorphic in character including nonulcerating hypopigmented macules nodular and erythematous eruptions verrucous growths and papillomas

Oriental Sore This disease is found in India the Near East Turkestan and the Mediterranean countries The incubation period varies from 2 weeks to as long as 3 years usually it is several months It is manifested by a localized granulomatous ulceration of the skin without pain or constitutional symptoms Lesions may be single or numerous and occur chiefly on the exposed surfaces of the body A typical sore begins as a pruritic erythematous papule gradually enlarges to a diameter of 4 to 8 cm ulcerates in the center and becomes secondarily infected with pyogenic organisms The crater fills with a discharge or a scab and is surrounded by a red indurated rim Even if untreated it heals in approximately a year leaving a smooth but conspicuous scar

American Cutaneous and Mucocutaneous Leishmaniasis (Espundia) This disease is found in tropical regions of Central and South America In it too there are one or more cutaneous granulomas similar to those of oriental sore and with a similar incubation period and clinical course However in as many as one fifth of patients serious metastatic mucous membrane manifestations appear in the form of eroding or nodular granulomatous lesions in the mouth nose pharynx larynx and trachea Rarely the genitalia and the eyes are involved The mucous membrane lesions usually appear months or years after the cutaneous lesions have already healed They progress slowly produce great pain disfigurement and debility and rarely heal spontaneously

Laboratory Diagnosis Specific diagnosis in leishmaniasis is established most readily by identifying the parasites in stained smears In kala azar they are most likely to be found in material aspirated from bone marrow or spleen they can also be found in liver lymph node cutaneous lesions and the leukocytic layer of blood In the cutaneous forms of the disease the organisms are present in scrapings of the local lesions or in the lymphatic structures which drain them Leishmaniae can be cultured from all these sources on special artificial media In espundia an intradermal skin test (Montenegro s test) is usually positive Certain hematologic and blood chemical changes occur in kala azar as outlined above

Treatment Visceral leishmaniasis responds very favorably to treatment with pentavalent antimony compounds including Neostibosan Solustibosan urea stibamine and a newer preparation called Pentostam An average course of treatment for an adult consists of 6 0 ml Pentostam intravenously daily for 6 days A group of drugs known as aromatic diamidines (including stilbamidine and pentamidine) are also potent therapeutic agents Because of their toxicity they are used only in patients resistant to antimonials Post kala azar dermal lesions are rather resistant to treatment and may require several courses of antimonials Diamidines are valueless

Therapy of oriental sore is somewhat less effective though healing eventually occurs spontaneously even in the absence of treatment Secondary pyogenic infection must be eradicated by appropriate use of antibiotics If the lesions are few in number they may be treated locally by the application of carbon dioxide snow or by periodic infiltration with a solution of berberine sulfate Pentostam emetine hydrochloride or quinacrine hydrochloride If the sores are numerous antimonials should be

Treatment There is good evidence in experimental infections that a combination of sulfonamide and 5-p-chlorophenyl 2 4-diamino-6-ethylpyrimidine (Daraprim) is somewhat better than sulfonamides alone Combinations of sulfadiazine or triple sulfonamides and Daraprim have been reported to yield excellent results in some cases of uveitis and to have affected others not at all The data on the effectiveness of this treatment in systemic toxoplasmosis are inadequate The combination is not specific for toxoplasmosis and the patient s response cannot be interpreted as proving or disproving a particular diagnosis The sulfonamide should be administered in the usual dosage along with 50 mg of Daraprim daily The dose of Daraprim probably ought to be decreased after 2 weeks to 25 mg One month of treatment constitutes an adequate trial Since Daraprim may induce severe leukopenia frequent leukocyte counts should be obtained during therapy and medication withdrawn if the leukocyte count becomes abnormal

Section 18 Diseases Caused by Worms

Gustave J Dammin

Progress in immunology epidemiology pharmacology and other fields has continued to improve our methods of diagnosis treatment control and prevention of the diseases caused by the helminths In the following chapters the effectiveness of Atabrine chloroquine and piperazine will be described More effective methods of field control of vectors have been devised as well as means of individual prophylaxis as in schistosomiasis Clinical and laboratory correlation has led to better definition of such entities as visceral larva migrans (Beaver) and pernicious tapeworm anemia" (von Bonsdorff) Important epidemiologic information has been gained from the work of Rausch on the life cycle and distribution of *Echinococcus multilocularis* in Alaska Publications have described the knowledge pertaining to the metabolism of the helminths and have helped to disseminate information on the important advances in therapy Contributions to these areas are being made by Weinstein and Weller on the in vitro development of larvae to the adult stage However there are other than the immediate medical problems which face the populations of these developing countries most of them tropical, where the helminthic infections are most prevalent. The poor economic status is reflected as well stated by Chandler by the need for "proper food, since malnutrition not only causes disease per se but is a very large factor in ability to fight other diseases and education because only by knowing what is dangerous and why can mankind help to win in the struggle with disease" The magnitude of the problem posed by these diseases has been well described It has been estimated that there are over 2,200 000 000 helminthic infections in the current world population of somewhat less than 2,200 000 000 The direction which control should take is emphasized by the observation that man has acquired over four fifths of these infections because of "ineffective insulation from his own excretory products" (Stoll)

The prevalence of helminthic disease in tropical areas is dependent in varying degree upon the following factors (1) the presence of appropriate vertebrate and invertebrate hosts (2) the higher temperature and humidity (3) poor personal hygiene (4) poor environmental hygiene and (5) particular racial food habits Some of these infections as they are observed in adult residents of endemic areas are usually mild and often asymptomatic This differs from the clinical picture produced in the initially exposed, in whom the infec-

fixing antibodies develop more slowly and disappear more rapidly Thus if a high dye test titer (1 256 or more) and a negative complement fixation re action are encountered one may be dealing with either an early acute infection or the residual sero logic status of past infection

An addition to the knowledge of the dye test is of special interest A positive reaction requires the presence of a heat labile serum factor It has now been demonstrated that this heat labile sub stance is in the properdin system Properdin all four components of hemolytic complement and magnesium are required This is the first instance when presence of the properdin system has been shown to be necessary for the action of a specific antibody

A skin test is available and may be performed with either antigen prepared from mouse peritoneal fluid or embryonated eggs The reaction is of the delayed type and cross reacting antigens have not been identified The egg antigen is preferable be cause suitable control material is available There are two drawbacks to the test as a diagnostic aid in an individual case (1) the number of reactors in the general population is large and (2) serum antibodies have been demonstrated in nonreactors If this test has any value it is in surveys where it may provide an index of the frequency of previous infections in a given area

Epidemiology Surveys performed with the skin and dye tests indicate that *Toxoplasma* infections are widespread About one half of the adult popu lations of Cincinnati Ohio and Syracuse N Y have been found to react positively

The dye test is a sensitive indicator of antibody Using this test it has been determined that ap proximately 33 per cent of the populations of a number of American cities and Haiti 63 per cent of Hondurans and 70 per cent of Tahitian natives are positive In contrast none of 20 Alaskan Eski mos was found to have antibodies and only 4 per cent of Navaho Indians and 11 per cent of a group of Icelanders had significant amounts of antibody Similar studies have been conducted among various animal species antibodies are especially frequent among dogs cats swine sheep goats guinea pigs and to a lesser extent rabbits and pigeons Al though the full significance of these findings re mains to be determined it is clear that serologic evidence indicates that infection with *Toxoplasma* may be abundant in man and many of his animal associates It must be emphasized that variations in prevalence are to be expected among all species The mode of transfer of parasites from animal to animal or to man is unknown there is no evidence for human to human transfer Human infection ap parently may be contracted in any season and with equal frequency by the two sexes

Clinical Manifestations Human infections with *Toxoplasma* may be either congenital or acquired On the basis of survey data referred to above it appears that acquired infections are frequently unapparent

An infant congenitally infected with *Toxoplasma* may be born prematurely or at term as a stillbirth or with an active infection manifested by various combinations of fever icterus rash hepatomegaly splenomegaly chorioretinitis convulsions and xan thochromic spinal fluid The newborn infant may have none of these signs but some time later hydro cephaly or microcephaly chorioretinitis convul sions psychomotor retardation and cerebral calcifi cation may be noted either singly or in combination A fatality rate of 11 per cent was noted in one series of 141 cases of congenital toxoplasmosis Among the more important evidences of disease in these children chorioretinitis was present in 94 per cent while 59 per cent had cerebral calcifica tions 45 per cent had psychomotor retardation and approximately half had either hydro or micro cephaly 39 per cent had convulsive episodes Thus the majority of patients had some permanent dam age The mothers of congenitally damaged offspring ordinarily are unaware of having had any specific illnesses during the pregnancy These women may undertake future pregnancies without fear of a recurrence in another child

In the proved cases of acquired toxoplasmosis the clinical features have shown considerable varia tion but certain manifestations are being recognized as suggestive of this disease Maculopapular rashes are not infrequent soon after the clinical onset of the illness and tend to disappear in 3 or 4 days Lymphadenopathy is common and local nodes may be so prominent as to suggest the possibility of Hodgkin s disease Encephalitis may be present alone or in combination with other manifestations Myalgias arthralgias myocarditis and pneumonitis also have been noted Siim has described a syn drome which resembles infectious mononucleosis in that lymphadenopathy lymphocytosis with atypi cal lymphocytes and negative Paul Bunnell reac tions may be present He has demonstrated parasites in lymph nodes removed from such patients some of whom have afebrile courses

Toxoplasma now have been isolated from cases of granulomatous uveitis presumably the result of acquired infections The proportion of such cases which is caused by *Toxoplasma* remains to be de termined and is still the subject of considerable investigation

There is still no reliable information concerning the incubation period recovery and mortality rates average duration of illness or residual defects re sulting from acquired toxoplasmosis Cerebral calci fications do not appear to follow this form

semble those produced by bacterial and other microbial agents As adults helminths do not multiply in the human host In this form their presence is usually made known by effects which are primarily mechanical The lumen of a hollow viscus or a duct system may be occluded (e g ascariasis fascioliasis) penetration of the intestinal wall to obtain a blood meal may lead to extensive blood loss (e g hookworm) or residence in the wall of a hollow viscus intra or extravascularly may lead to ulceration and blood loss (strongyloidiasis schistosomiasis) As larvae some helminths produce symptoms during penetration of the skin and migration to their site of definitive development There is a similarity between helminthic and microbial infections with reference to the immunologic response of the host In both precipitins complement fixing skin sensitizing and neutralizing antibodies have been demonstrated Tests for immunologic response have diagnostic value in trichinosis *Echinococcus* disease filariasis and schistosomiasis

Attention is focused on the helminthic diseases of man when because of war or other circumstances troops stationed in endemic areas are exposed to these hazards and there is danger of having new or more virulent forms of disease brought by servicemen to nonendemic areas In American army personnel during the Second World War there were reported 2 151 hospital admissions for filariasis and 1 636 for schistosomiasis primarily japonica but the number of infections was undoubtedly considerably greater The number of military personnel contracting hookworm infections in some endemic areas was large but difficult to estimate Because of the presence in the United States of appropriate mosquito hosts the possibility exists that filariasis may again be established here A species of *Tropicorbis* capable of acting as intermediate host for *Schistosoma mansoni* has been encountered in Louisiana More likely is the establishment of *Ancylostoma duodenale* in the southern United States by those returning from the Pacific and Asiatic areas of combat The Korean War kept alive an interest in these problems However as one views the scope and methods of instruction used in the teaching of the helminthic and parasitic diseases in general it is apparent that these diseases are not recognized as the global problems they represent Nor are these diseases recognized as unique problems in host parasite relationships and ecology These aspects should be stressed The importance given these diseases in the curriculum should not be related to their importance in our immediate populations

The important helminths are members of the phyla Platyhelminthes and Nemathelminthes The diseases they produce and their habitats in the human host are tabulated on page 1118

HOOKWORM DISEASE

Definition Hookworm disease is a symptomatic infection caused by *Ancylostoma duodenale* and/or *Necator americanus* Asymptomatic infection may be simply termed *hookworm infection* and the individual with such infection a *carrier*

Etiology *Ancylostoma duodenale* also known as the Old World hookworm possesses four prominent hooklike teeth in its adult stage The male measures about 1 cm in length and presents a characteristic copulatory bursa The adults inhabit the upper small intestine of man They attach to the mucosa by means of the mouth parts and suck blood Each adult daily extracts about 0 5 ml of blood The adults migrate within the small intestine and each site of attachment persists temporarily as

Phylum	Class	*Disease*	*Causal agent*	*Stage and habitat in man*
Nemathelminthes	Class Nematoda	Hookworm	*Necator americanus*	Adults in intestine
			Ancylostoma duodenale	Adults in intestine
		Creeping eruption	*Ancylostoma braziliense*	Larvae in skin
			Uncinaria stenocephala	Larvae in skin
		Strongyloidiasis	*Strongyloides stercoralis*	Adults in intestine
		Trichostrongyliasis	*Trichostrongylus* spp	Adults in intestine
		Ascariasis	*Ascaris lumbricoides*	Adults in intestine
		Trichuriasis	*Trichuris trichiura*	Adults in intestine
		Enterobiasis	*Enterobius vermicularis*	Adults in intestine
		Trichinosis	*Trichinella spiralis*	Early Adults in intestine Late Larvae in muscles
		Filariasis bancrofti	*Wuchereria bancrofti*	Adults in lymphatics Larvae in blood
		Filariasis malayi	*Wuchereria malayi*	Adults in lymphatics Larvae in blood
		Onchocerciasis	*Onchocerca volvulus*	Adults and larvae in skin subcutaneous and other tissues
		Loiasis	*Loa loa*	Adults migrate in subcutaneous tissues larvae *in blood*
		Dracunculiasis	*Dracunculus medinensis*	Adults in skin and subcutaneous tissue
Platyhelminthes	Class Trematoda	Schistosomiasis mansoni	*Schistosoma mansoni*	Adults in portal and intestinal veins
		Schistosomiasis japonica	*Schistosoma japonicum*	Adults in portal and intestinal veins
		Schistosomiasis haematobia	*Schistosoma haematobium*	Adults in veins of the urinary bladder
		Schistosome dermatitis	Nonhuman schistosomes	Larvae in skin
		Fascioliasis	*Fasciola hepatica*	Adults in bile ducts
		Clonorchiasis	*Clonorchis sinensis*	Adults in bile ducts
		Opisthorchiasis	*Opisthorchis felineus*	Adults in bile and pancreatic ducts
		Paragonimiasis	*Paragonimus westermani*	Adults in lungs
		Fasciolopsiasis	*Fasciolopsis buski*	Adults in intestine
	Class Cestoda	Diphyllobothriasis	*Diphyllobothrium latum*	Adults in intestine
		Taeniasis saginata	*Taenia saginata*	*Adults in intestine*
		Taeniasis solium	*Taenia solium*	Adults in intestine occasionally cysticerci in tissues
		Echinococciasis	*Echinococcus granulosus*	Larval form in liver lungs and other organs
		Hymenolepiasis	*Hymenolepis nana*	Adults in intestine
		Dipylidiasis	*Dipylidium caninum*	*Adults in intestine*
		Sparganosis	Migrating larvae of *Diphyllobothrium* spp	Larvae in subcutaneous tissues

tions are more often severe The immunologic basis for these differences can only be inferred from experimental studies What is apparent is the greater significance which a positive laboratory finding (a helminth at some stage of its life cycle) has in relation to clinical findings in initially exposed individuals In reference to clinical findings per se in few of these diseases are they such as to lead to a specific diagnosis By themselves the clinical findings may suggest a presumptive diagnosis but the definitive diagnosis must invariably be made in the laboratory However even with a positive report from the laboratory the clinician must be cautious in evaluating the role of the parasite in the clinical picture presented For example the presence of hookworm eggs in the feces does not make the diagnosis hookworm disease A distinction must be made between asymptomatic infection and symptomatic infection or disease Nor does a negative direct stool examination rule out disease caused by blood or intestinal helminths When direct microscopic examinations of selected portions of entire stool specimens are negative appropriate concentration methods should be applied Only after thorough laboratory study occasionally requiring the examination of material obtained by proctoscope as in suspected schistosomiasis or duodenal drainage in suspected *Fasciola hepatica* or *Clonorchis sinensis* infection may a final decision be possible The proper investigation of suspected helminthic infections requires of the clinician a general knowledge not only of clinical manifestations but also of epidemiology helminthic life cycles and laboratory procedures

Brief mention should be made of the manner in which helminthic infection

sult from institution of a balanced high protein diet and in the treatment of severe infection it is essential that the utmost improvement from proper diet be attained before drug therapy is begun

Asymptomatic infection or the carrier state is common in endemic areas where asymptomatic outnumber symptomatic infections considering all age groups 20 to 40 times The worm burden is small and in these areas the carrier state is probably indicative of some degree of acquired host resistance

Laboratory Findings In symptomatic infection hookworm eggs are usually numerous enough to be detected by microscopic examination of a direct fecal smear It must be borne in mind that abdominal symptoms and pulmonary symptoms appear before eggs are discharged although a presumptive diagnosis may be made on the basis of the clinical history and the eosinophilic leukocytosis

The feces seldom contain gross blood in hookworm disease although usually positive for occult blood Charcot Leyden crystals are found in the feces in one half to two-thirds of the cases

Trichostrongylus eggs must be distinguished from hookworm eggs The former are larger and in a later stage of maturation when observed in a fresh fecal specimen

Generally the leukocyte count is normal or slightly elevated and the percentage of eosinophils increased to 15 or 30 per cent However in some early cases the leukocytosis may be marked and the eosinophil percentage as high as 70 or 80 per cent In such cases a diagnosis of eosinophilic leukemia has been entertained In general the more marked the anemia the lower the percentage of eosinophils The anemia is characteristically of the hypochromic microcytic variety

Differential Diagnosis Since hookworm disease occurs in areas in which beriberi and malaria in their cachectic forms are also more common these diseases must be differentiated from hookworm disease or their coexistence established

Treatment Specific therapy for the infection and that directed toward improvement of the nutrition and anemia should be considered simultaneously In the usual case with slight to moderate anemia anthelmintics can be administered followed by iron therapy (ferrous gluconate or ferrous sulfate) and a high protein balanced diet The current drug of choice is tetrachlorethylene although hexylresorcinol carbon tetrachloride and oil of chenopodium are useful under particular circumstances Tetrachlorethylene in hard gelatin capsules is given as a single dose oral treatment 3 ml being the dose for adults For children 0 2 ml is given for each year of age The night before treatment is to be given the patient is permitted a light fat free meal The following morning breakfast is omitted and the drug administered No food is permitted for 4 hr no alcohol for 24 hr Sodium sulfate (30 Gm in a glass of water) is given 4 hr after the tetrachlorethylene Ascariasis however if also present must be treated first with piperazine citrate (Antepar) hexylresorcinol or Hetrazan since tetrachlorethylene increases the activity of the ascarids Hexylresorcinol particularly when given in several courses of treatment as for ascariasis may simultaneously control concomitant ascarid and hookworm infections making other treatment unnecessary Piperazine citrate which is effective in ascariasis is not effective in hookworm infection

Carbon tetrachloride and oil of chenopodium are no more effective and are more toxic to the host than tetrachlorethylene and hexylresorcinol However they are less expensive and simpler to administer since they are given in liquid form thus making them useful for mass treatment

The aim in treatment is reduction of the worm burden to an asymptomatic level Eradication is difficult particularly in *Ancylostoma* infection

When anemia is severe and malnutrition with anasarca are also present blood transfusions and a high protein balanced diet should be given before drug treatment is begun In such cases the blood should be given in small increments and in a total amount sufficient to raise the hemoglobin level to 9 to 10 Gm per 100 ml In advanced cases it may be necessary to delay drug treatment for 2 to 3 weeks

Prognosis Generally the immediate prognosis is good When opportunity for reinfection persists and nutrition cannot be maintained a state of chronic debility develops In children development is impaired and in adults intercurrent disease proves serious

Prevention Many of the measures required are obvious but difficult to apply on a large scale Even if facilities for proper disposal of feces are provided it is no simple matter to educate the population in their use Soil pollution must be eliminated and until this is accomplished avoidance of direct skin contact with the soil (as by wearing of shoes) should be encouraged Periodic mass treatment of the population has been used in some hookworm control programs

CREEPING ERUPTION (Cutaneous Larva Migrans)

Definition Creeping eruption is an infection of the skin in man caused by the larvae of the dog and cat hookworm *A braziliense* The other dog hookworms *A caninum* and *Uncinaria stenocephala* and the horse botfly *Gasterophilus* in

a bleeding point Following fertilization the female liberates eggs which measure about 40 by 60 μ and are usually in the two to four celled stage when discharged in the feces

Necator americanus the "New World hook worm has a buccal capsule containing dorsal and ventral plates rather than teeth

The life cycles of these hookworms are similar Following development to the filariform or infective stage the larvae are capable of penetrating the skin to enter vessels which carry them to the lungs The larvae leave the alveolar capillaries and enter the alveoli They ascend the respiratory tree enter the pharynx and are swallowed They reach the intestine about 1 week after penetration of the skin and 3 or 4 weeks later are mature The adults have been known to survive in the human intestine for 5 years

Epidemiology Environmental conditions conducive to the development of the hookworm egg into the infective filariform larval stage are found in tropical and semitropical regions in which adequate rainfall occurs Given the appropriate environmental conditions hookworm infection will occur where there is opportunity for contact of the skin with contaminated soil Infection can be acquired by ingestion of filariform larvae but this mode of transmission is of little importance That development of hookworm eggs into the filariform larval stage can occur in contaminated bedclothes has been shown and also that fomites borne hookworm infection may be of importance

The white race is more susceptible to symptomatic infection than the Negro the latter still constituting however an important reservoir of infection Probably because of greater exposure males show a higher incidence of infection than females

Regarding the relative importance of the two hookworms it has been stated that "*Ancylostoma* presents a greater public health problem than *Necator americanus* the species now established in the southern United States because it is more harmful to the host is less amenable to treatment and its free living stages are more resistant to climatic conditions" (McCoy)

Pathogenesis and Clinical Manifestations The nature and severity of the clinical manifestations are determined by the stage and intensity of the infection During the invasion of the exposed skin by the larvae the affected parts become erythematous and edematous and there is severe pruritus These manifestations are more marked in *N americanus* infection than in *A duodenale* infection The lesions are commonest about the feet particularly between the toes and have been termed ground itch"

During passage of the larvae through the lungs cough and in severe infections fever are observed The pulmonary symptoms were particularly troublesome to soldiers engaged in close combat in the Asiatic campaign in the Second World War

Epigastric pain abdominal tenderness and occasionally vomiting and diarrhea can be prominent symptoms during the establishment and migration of the hookworms in the small intestine Roentgenographic studies at this stage may reveal a "cog wheel pattern of the upper small intestine presumably produced by the mucosal involvement As hookworm disease was observed in American troops in northern India and Burma where *A duodenale* infection predominates it was during this phase of the disease that medical aid was sought Eosinophilic leukocytosis was present but anemia was not nor did it develop presumably because of the short duration of the infection and early treatment Judging from the number of adult hookworms collected from posttreatment fecal specimens these were relatively light infections They were predominantly *A duodenale* infections which are generally accepted as being more severe than those caused by *N americanus* Clinical observations on induced *A duodenale* infections have been reported by Brumpt

The clinical picture which has been described as classic occurs in residents of endemic areas and differs from the above in that anemia with symptoms and visceral changes incident to the anemia are dominant The severity of the disease and the prognosis are dependent upon such factors as the age of the patient the magnitude of the worm burden the duration of the disease and diet Young children more often manifest the extreme anemia with cardiac insufficiency and anasarca The anemia usually develops slowly and results from loss of blood—that which the hookworm sucks and ingests and that which oozes into the intestinal lumen after the hookworm has left the site of mucosal attachment Patients may have a depraved appetite with a desire to eat coarse or gritty materials Those who survive to puberty show a retarded physical mental and sexual development Milder degrees of the disease as seen in older children and adults are characterized by lassitude dyspnea palpitation tachycardia and constipation in addition to the pallor of the skin and mucous membranes In most areas in which hookworm disease is common dietary deficiencies are also common Poor diet influences unfavorably the course of hookworm disease Study of hookworm infection in the dog has shown that host control of infection depends largely upon the development of immunity and that immunity does not develop or may be lost in the presence of malnutrition avitaminosis and anemia In man considerable clinical improvement can re

myocardium lungs trachea liver and gallbladder in addition to the intestine In other fatal cases intestinal perforation and peritonitis have been encountered

Laboratory Findings Although the nature of the clinical findings may be suggestive the definitive diagnosis must be made in the laboratory Fresh fecal specimens should be examined to avoid confusion with hookworm infection generally fresh specimens contain larvae in strongyloidiasis infections while in hookworm infection they contain eggs When pulmonary involvement is present the sputum should be examined for larvae Microscopic examination of the duodenal washings may readily establish the diagnosis It should be performed when other studies are negative and in determining the efficacy of treatment

Eosinophilic leukocytosis is common except in very severe cases in which eosinophilic leukocytes may be entirely absent

Treatment Gentian violet administered orally continues to be the most satisfactory treatment although it is only moderately effective It is given in capsules (1½ hr coating) with meals 0 06 Gm t.i.d for 10 to 14 days Nausea occasionally with vomiting and diarrhea may appear during the course of treatment Such manifestations may make it necessary to discontinue oral treatment When the oral route of administration cannot be tolerated or when it proves ineffective and further treatment is indicated gentian violet may be given by duodenal tube (25 ml of 1 per cent solution) For severe hyperinfective cases gentian violet has been given intravenously (25 ml of 0 5 per cent solution) Careful and prolonged posttreatment laboratory study is necessary to determine effectiveness of the drug in each case

Initial results with Nilodin (lucanthone hydrochloride) which is a thioxanthone derivative have been encouraging enough to merit further evaluation

Prognosis In the usual case the prognosis is good Since the occurrence of hyperinfection is unpredictable every effort should be made to eradicate the infection in each case In severe cases with hyperinfection the prognosis is poor

Prevention In general the measures are those for the control of hookworm infection In addition it is well to remember that infection may be contracted by ingestion of contaminated food (especially uncooked vegetables) or of contaminated drinking water and by contact

ASCARIASIS

Definition Ascariasis is an infection of man caused by *Ascaris lumbricoides* and characterized by an early transient pulmonary phase related to larval migration and a later prolonged phase during which the adult ascarids inhabit the lumen of the intestine

Etiology The adult ascarids are large (20 to 40 cm in length) and cylindric in shape with each extremity tapering to a blunt point Their usual habitat is the small intestine but they are prone to migration The eggs are elliptic (30 to 40 μ by 50 to 60 μ) and have an irregular dense outer shell and a regular translucent inner shell They are not infective upon discharge from the body Under proper conditions of warmth and moisture the ovum develops to the infective larval stage in about 4 to 5 weeks Upon ingestion of the egg at this stage the larva is liberated in the small intestine It migrates through the wall and ultimately reaches the lungs After about 10 days in the pulmonary capillaries and alveoli the larvae pass in turn to the bronchioles bronchi trachea and epiglottis are swallowed and develop into male and female adults in the small intestine

Epidemiology and Distribution Infection follows the ingestion of the embryonated egg contained in contaminated food or more commonly the introduction of the eggs into the mouth by the hands after contact with contaminated soil Since the eggs are resistant to desiccation and wide variations in temperature the disease has a world wide distribution

Pathogenesis and Clinical Manifestations Because of the extensive migration of which both the larvae and adults are capable clinical manifestations may be unusually diverse In heavy infections severe bronchopneumonia occasionally fatal in children can occur during the migration of the larvae through the lungs Light infections assume importance when single or several adult ascarids obstruct the appendix the bile the pancreatic ducts or other hollow structures of the upper intestinal or respiratory tracts

Laboratory Findings The diagnosis is usually made by finding the ova in the feces The intact ova are characteristic and not easily confused with other ova

Symptomatic infection especially during the phase of larval migration through the lung is usually accompanied by fever and eosinophilic leukocytosis

Treatment Only symptomatic treatment can be used during the period of pulmonary involvement by the migrating larvae For removal of the adult worms from the intestines piperazine citrate as a flavored syrup administered in a single dose after breakfast on two successive days will cure 94 per cent of cases (Brown) For younger children (30 to 50 lb) 2 Gm piperazine equivalent contained

their larval stage may produce a similar cutaneous infection

Etiology The adult stage of *A brasiliense* occurs regularly only in the dog and cat The larvae emerging from eggs discharged in the feces develop to the filariform stage and then are capable of penetrating the skin In man the larvae usually remain in the skin and migrate producing an irregular erythematous tunnel visible on the skin surface

Epidemiology and Distribution Dogs and cats constitute the reservoir of infection for man Transmission among animals and to man requires environmental temperature and humidity appropriate for development of the egg to the infective filariform larva stage Such conditions are found in the southeastern United States coastal areas of Central America northern South America northern and southern Africa and some areas of the Far East Beaches and other moist sandy areas are hazardous because animals choose such areas for defecation and the *A brasiliense* eggs develop well in such soil

Pathogenesis and Clinical Manifestations The site of penetration of the skin by the larva becomes apparent in a few hours The hands feet and legs are most frequently involved The migration of the larva in the skin is accompanied by severe itching Scratching may lead to bacterial infection In the course of one week the initial red papule develops into an irregular erythematous linear lesion which may attain a length of 15 to 20 cm Development of *A brasiliense* to the adult stage occurs rarely in man

Wright and Gold have observed Loeffler's syndrome in 26 of 52 cases of creeping eruption Transient migratory pulmonary infiltrations were associated with an increase in eosinophils in the blood and sputum The lesions have been interpreted as an allergic reaction to the helminthic infection

Laboratory Findings Eosinophils occur in the lesion but eosinophilic leukocytosis is slight except when Loeffler's syndrome appears The percentage of eosinophils in the blood may then rise to 51 per cent and in the sputum to 90 per cent

Treatment Carbon dioxide snow or ethyl chloride spray may be applied locally to destroy the larva Superficial bacterial infections are improved by wet dressings and elevation of the extremity

Prognosis Untreated infections may last several months Treatment is usually sought because of severe pruritus and moderate incapacitation The above treatment is usually successful

Prevention Dogs and cats should be prevented from contaminating recreation areas Contact of the skin with the soil should be avoided in areas suspected of being contaminated

STRONGYLOIDIASIS

Definition Strongyloidiasis is an intestinal infection of man and other higher mammals caused by *Strongyloides stercoralis*

Etiology The adult female resides in the mucosa of the upper small intestine The embryonated eggs soon develop into the rhabditiform larvae in which form they are observed in the feces Further larval development may take one of several courses (1) In a suitable external environment the indirect or sexual cycle occurs (2) Under less suitable external circumstances the rhabditiform larvae develop into the infective filariform stage (direct or asexual cycle) (3) Development to the infective stage is presumed to occur as well in the lower intestine the filariform larvae then entering the body through the skin of the perineum or through the intestinal wall Mechanisms such as those mentioned in (3) above may explain the long periods of infection observed (20 to 30 years) in those who have left endemic areas

The course of the filariform larvae of *S stercoralis* after entering the skin the oral mucosa or the intestinal mucosa resembles that of the hookworm larvae In the intestine the females burrow into the mucosa from which site embryonated eggs are discharged

Epidemiology and Distribution The usual mode of infection is the penetration of the skin by larvae present in contaminated soil Some infections may result from ingestion of contaminated food and drink and some are believed to be transmitted by contact

Endemic areas are found primarily in the tropics although sporadic cases have appeared in temperate regions

Pathogenesis and Clinical Manifestations Erythema with petechiae and pruritis characterizes the site of cutaneous penetration by the larvae Cough occasionally with dyspnea and hemoptysis accompanies the stage of migration through the lungs X rays may exhibit pulmonary infiltration at this stage

Epigastric pain and tenderness nausea flatulence and vomiting as well as diarrhea alternating with constipation may be observed during the intestinal phase of development The diarrhea may persist for long periods causing excessive loss of fluid Intestinal ulceration and sloughing are noted in severe cases As with hookworm infection many asymptomatic infections occur and most symptomatic infections occasion only vague complaints

In massive infection there may be serious complications The extensive involvement possible is illustrated by the fatal case described by Kyle et al in which extensive pulmonary hemorrhage and edema were observed Larvae were found in the

as 97 per cent of cases when prescribed in a single course of 7 days It is given in syrup form each day before breakfast with total daily dose of 250 mg for children weighing up to 15 lb 500 mg for those weighing between 16 and 30 lb 1 Gm for those between 31 and 60 lb and 2 Gm for those over 60 lb (Brown) When renal insufficiency is present the piperazine should be given in smaller dosage to avoid neurotoxicity

Prognosis The prognosis with reference to the duration of infection is good particularly when the other measures mentioned are carried out in addition to drug treatment

Prevention Methods of preventing autoinfection and dissemination within a group involving children are difficult to apply Personal and environmental hygiene should be stressed and anthelmintic and symptomatic treatment of pruritus are instituted To control infection within a group simultaneous treatment of all cases must be carried out

TRICHURIASIS

Definition Trichuriasis (whipworm infection trichocephaliasis) is an intestinal infection of man caused by *Trichuris trichiura* and is characterized by invasion of the colonic mucosa by the adult *Trichuris*

Etiology The adult whipworms possess a thread like anterior two thirds and a stouter posterior third giving them a whiplike structure The eggs are characteristic being barrel shaped brown and translucent and having knoblike extremities

Epidemiology The mode of spread resembles that of ascariasis the eggs generally being introduced into the mouth by contaminated fingers

Pathogenesis and Clinical Manifestations Symptomatic infection generally requires the presence of large numbers of adult whipworms and may be correlated in part with the degree of mucosal involvement Heavy infections usually occur only in children and may be accompanied by nausea abdominal pain and diarrhea

Laboratory Findings In symptomatic infection large numbers of eggs are present in the feces Eosinophilic leukocytosis and anemia may accompany such infections

Treatment The most readily available and least toxic drug although not highly efficient is hexylresorcinol The evening before the drug is to be administered the meal should be light and breakfast should be omitted In the morning hexylresorcinol is given orally in hard gelatin capsules the dose for children being 0 1 Gm for each year up to the age of ten and for older children and adults 1 Gm The hexylresorcinol capsules are swallowed without chewing since hexylresorcinol is irritating to mucosal surfaces A saline purge e g sodium sulfate is given 2 to 3 hr after administration of the drug and no food eaten for 4 to 6 hr This procedure should be repeated in 4 to 5 days If the worm burden has been appreciably reduced no further treatment is necessary

When involvement of the colon is extensive as judged by the clinical symptoms and/or the worm burden hexylresorcinol should be given as an initial treatment in the form of a retention enema (one half to one liter hexylresorcinol in 0 1 per cent aqueous solution) Petroleum jelly is applied to the perineum to prevent cutaneous irritation by the hexylresorcinol

If heavy infection persists piperazine citrate as recommended for enterobiasis may be used

Prognosis In uncomplicated *Trichuris* infection the prognosis is good Symptomatic infection can be controlled with the drugs mentioned although eradication of the infection is difficult

Prevention Measures recommended for ascariasis apply also to trichuriasis

TRICHOSTRONGYLIASIS

Definition Trichostrongyliasis is an intestinal infection of man and other mammalian hosts including sheep goats and cattle

Etiology Almost a dozen species of *Trichostrongylus* are known to have infected man Few human infections have been reported in the United States In view of the high frequency of animal infections here the low incidence of human infections is difficult to understand The possibility exists that some may be diagnosed as hookworm infection

The ova resemble those of the hookworm but are larger and when observed in a fresh fecal specimen show a more advanced stage of segmentation (16 to 32 celled stage)

Pathogenesis Infection is acquired by ingestion of the larvae rather than by their penetration of the skin The adult maintains residence in the intestine for long periods Sandground who infected himself observed infection to last more than 8 years

Manifestations Diarrhea is observed occasionally when infection is massive but most infections are asymptomatic The parasite owes its importance primarily to the resemblance of its ova to those of the hookworms Moreover because the trichostrongylidae do not respond to anthelmintics effective in hookworm infection it may be assumed incorrectly that one is dealing with refractory hookworm infection

Laboratory Diagnosis The diagnosis depends upon the finding of the ova in the feces Since they are few in number they are usually found only when a concentration method is used In symp

in 20 ml syrup constitutes each dose for older children and adults 3 to 3 5 Gm is given No particular dietary regulation is necessary The drug *must be administered with caution when renal* insufficiency is present since impaired elimination may produce neurotoxic signs

Prognosis The prognosis in intestinal infection is generally good When acute or chronic obstruction of ducts or hollow viscera has occurred the im mediate prognosis is determined by the promptness in diagnosis and treatment

Prevention Ascariasis is primarily a household infection of rural areas All infections should be treated personal hygiene stressed and adequate toilet facilities provided

VISCERAL LARVA MIGRANS

This is a clinical syndrome usually observed in children and characterized by hepatosplenomegaly skin rash and recurrent pneumonitis with respira tory distress in the form of wheezing There is generally a history of dirt eating and contact with dogs or cats in or near the household Ocular in volvement and central nervous disturbances in the form of convulsions may also be observed

Leukocytosis with eosinophilia to high levels (over 60 per cent) and hypergammaglobulinemia are common The eosinophilic leukocytes are un usual in that they are large and have vacuolated cytoplasm containing granules which vary in size and are present in smaller than normal numbers

This syndrome with various degrees of clinical severity follows the ingestion of the infective eggs of nematodes whose life cycle is not completed in man It is caused most often by nematodes whose life cycle is completed in the dog (*Toxocara canis*) or in the cat (*Toxocara cati*) Larvae of the *Toxo cara* become widely disseminated in the body and incite a granulomatous reaction Lesions are promi nent in the liver lungs skeletal muscle and brain Larvae with eosinophilic leukocytic and granulo matous reactions have been noted in liver biopsies

The clinical diagnosis may be made on the basis of the findings described Immunologic tests are helpful but at this time do not have sufficient speci *ficity to be diagnostic Visceral larva migrans is an* other variety of helminthic infection capable of causing Loeffler s syndrome When the respiratory *difficulty is pronounced ACTH or adrenal cortical* steroids may prove helpful There is no particular treatment for the other lesions

In control measures are directed toward pre *venting* ingestion of the *Toxocara* eggs Removal or repeated treatment of infected cats and dogs must be considered as well as modifying the diet to reduce the temptation to ingest contaminated ma *terials*

ENTEROBIASIS

Definition Enterobiasis (pinworm seatworm or threadworm infection oxyuriasis) is an intestinal infection of man caused by *Enterobius vermicularis* and characterized by perianal pruritus

Etiology The adults are small fusiform worms usually inhabiting the cecum and colon attached to the mucosa The female averages 10 mm in length the male 3 mm The eggs are deposited by the female on the perineal skin the migration gen *erally occurring at night Each egg contains an em* bryo which a few hours after being deposited develops into the infective larva After ingestion of the egg the larva is released in the small intestine *The adult stage* is soon reached and in *less than* 1 month from the time of ingestion newly devel oped gravid females are again discharging eggs They are planoconvex and measure approximately 20 by 50 μ The shell is clear and doubly contoured

Epidemiology and Distribution The eggs usu ally reach the mouth of the human host by way of contaminated hands food or drink although air borne transmission may also occur They are relatively resistant to desiccation and because they are infective soon after discharge from the body transmission within family and children s groups occurs readily Enterobiasis is found in all climates and is probably the commonest helminthic infection of man Its low incidence in some tropical areas however defies explanation

Clinical Manifestations The commonest symp tom is pruritus ani which is most troublesome at night being related to the migration of the gravid female worms Scratching may lead to perineal eczema or pyogenic infection

Laboratory Findings Examination of material obtained from the perineal skin for ova by means of a cellophane or Scotch tape swab is essential for the detection of enterobiasis Less than 5 per cent of infections are diagnosed by searching for ova in the feces Scrapings from under the nails may *reveal ova The diagnosis* can be made by exam ining the feces for adult worms following a laxa tive or an enema Eosinophilic leukocytosis is in constant

Treatment All infected individuals in an affected *communal group should* be treated simultaneously The aim in drug treatment is reduction of the worm burden Drug treatment combined with such meas *ures as* (1) providing a sleeping garment which prevents contamination of the fingers with ova from the perianal region (2) instituting a morning shower (3) lukewarm water enemas and (4) local antipruritic ointments is directed toward producing asymptomatic infection with eradication or cure not the immediate objective

The preferred therapeutic agent is piperazine citrate which has been found effective in as high

other parts of the world In the United States where the incidence is between 15 and 20 per cent there is "more than three times as much trichinosis as is known in all of the rest of the world put together" Studies show that this high incidence has continued The ratio of asymptomatic to symptomatic infection is high

Pathogenesis and Clinical Manifestations The course and symptomatology vary remarkably The clinical diagnosis in the sporadic case may be difficult Diarrhea is an early manifestation related to the development of the adults in the intestinal mucosa and is observed in about half of the cases It usually appears within 24 hr after ingestion of the uncooked or undercooked meat containing the encysted larvae The next stage that of muscular invasion begins about the end of the first week and may last for as long as 6 weeks Most of the clinical manifestations are related to the invasion and encystment of the larvae in skeletal muscles A myositis is produced with basophilic granular degeneration of the invaded muscle fiber Adjacent fibers exhibit hyaline or hydropic degeneration and the focus becomes infiltrated with neutrophilic and eosinophilic leukocytes some lymphocytes and mononuclear macrophages Hyperemia edema and hemorrhages are constant features

Larvae do not encyst in cardiac muscle nor can they be found readily there Despite this an intense myocarditis has been observed and may be of significance in fatal cases

Larvae have been observed in association with less severe focal lesions in the lungs and brain and in other viscera with no associated inflammatory reaction

The significant clinical manifestations are noted during the period of migration and muscle invasion Fever is probably the commonest manifestation Ocular manifestations may be among the most striking The edema of the eyelids often accompanied by conjunctivitis and chemosis is difficult to explain but may be related to larval invasion of the eye muscles and possibly other retrobulbar tissues Also a constant manifestation is the muscular pain and tenderness Electromyograms have disclosed extensive fibrillation Manifestations in the skin and appendages include (1) a maculopapular rash which usually lasts for several days and (2) subungual "splinter hemorrhages"

Laboratory Findings The most constant finding and one of significance early in the course of the disease is the eosinophilic leukocytosis (over 500 eosinophilic leukocytes per cubic millimeter) It appears generally before the end of the second week and rises In cases of moderate severity the percentage of eosinophilic leukocytes ranges between 15 and 50 per cent In severe cases particularly ter

FIG 150 *Trichinella spiralis* Larva encysting within a skeletal muscle fiber At this stage myositis and edema have partially subsided (×135)

minally the eosinophilic leukocytes may disappear entirely

The skin test becomes positive early in the third week of infection The antigen is prepared from larvae and used in a dilution of about 1 10 000 One one hundredth of a milliliter is injected intradermally and immediate and delayed reactions looked for The usual positive response is immediate a wheal of 5 mm or more appearing within 30 min Nonspecific reactions may be related to the ingestion of meat containing nonviable trichinae

The precipitin reaction becomes positive after the third week Its value in diagnosis is increased if the reaction is initially negative and becomes positive or if the titer rises during the course of the disease It remains positive for about a year

In attempting to arrive at a definitive diagnosis examination of the feces for the adult worms is of little help Examination of the blood cerebrospinal fluid or muscle biopsy is more rewarding Microscopic study of laked venous capillary or arterial blood is the simplest test which may make a definitive diagnosis possible Larvae have been found in the peripheral blood as early as the fifth day in experimental infections Larvae may be present in the cerebrospinal fluid in the absence of clinical central nervous system involvement Biopsied muscle is best studied by use of a compressor which permits examination of the entire specimen Maceration and digestion methods are used in survey

tomatic infections there may be leukocytosis with marked eosinophilia (e g 80 per cent)

Treatment Piperazine citrate as recommended for enterobiasis has given good results

Prevention Contamination of the hands and food grown in contaminated soil are to be avoided

199 TRICHINOSIS

Gustave J Dammin

Definition Trichinosis is caused by the intestinal nematode *Trichinella spiralis* As a clinical infection it is characterized by diarrhea during the development of the adults in the intestine and by myositis *with systemic reaction during the larval migration* and invasion of the skeletal muscles

Etiology and Epidemiology Infection is contracted following ingestion of meat containing the encysted larvae of *T spiralis* There are no intermediate hosts both the adult and larval stages developing in the same host *Trichinella spiralis* exhibits little host specificity infection having been *produced or observed in the bear wild boar* horse cow dog cat rabbit guinea pig mouse and marine mammals in addition to the rat and the pig Man is particularly susceptible most fowl are resistant Among pigs infection is contracted following feeding of uncooked pork scraps less often by eating infected rats Rats also feed on uncooked pork scraps and in addition maintain a high inci*dence of infection by their cannibalism*

Soon after liberation of the larvae from their cysts they migrate into the mucosa and within a week the viviparous female is discharging *larvae* (100 by 6 μ) which enter vascular channels and are distributed throughout the body Larviposition continues for about 4 to 6 weeks The larvae enter skeletal muscle and encyst (Fig 150) The muscles of the diaphragm tongue and eye the deltoid pectoral and intercostal muscles are most often affected Larvae carried to sites other than skeletal *muscles do not encyst but disintegrate* The life cycle can be carried further only if a new host ingests the encysted larvae

Geographic Distribution Trichinosis is common in Europe and North America and uncommon in

periodic in W bancrofti infections peak concentrations being between 9 P M and 2 A M Wuchereria malayi is similarly but less regularly periodic In many western Pacific islands including Samoa and Fiji W bancrofti is nonperiodic the reason for this is entirely unknown The danger of infection in the periodic disease is nocturnal but the non periodic form is often transmitted by sylvan mosquitoes in natural cover during the day

Wuchereria bancrofti infection is endemic between latitudes 41 N and 30 S Distribution is irregular and there are many peculiar skip areas" in this geographic pattern presumably because the endemic disease can be maintained only where human infection and mosquitoes are prevalent *Wuchereria malaya* infection is confined to the Far East including India Malaya East China and the Philippines There were approximately fifteen thousand *W bancrofti* infections among American military personnel in the Second World War (Wartman)

A small endemic focus of *W bancrofti* once existed near Charleston S C but no new cases have been observed in several years

Pathogenesis As larvae migrate to the lymphatics they produce irritation whether by some secretion or entirely by hypersensitivity responses of the host being unknown The larvae reach maturity in lymph nodes and incite hypertrophy granulomatous inflammation and obstruction often with retrograde lymphangitis Repetition of this process for many years can lead to permanent blockage scarring and elephantiasis Secondary bacterial infection is thought by some to be important in the etiology of elephantiasis but this has not been established Elephantiasis is actually a relatively unusual complication of filarial infections If repeated reinfections do not occur the disease is self limited

Manifestations Acute filariasis manifests itself as a series of brief attacks over a period of weeks Symptoms vary greatly in severity and include headache fatigability vertigo photophobia and muscle pain Fever is low grade and chills are rare in the early stages Examination shows lymphadenopathy streaks of lymphadenitis and sometimes circumscribed reddish swellings of the extremities The male genitalia are frequently involved with epididymitis orchitis hydrocele or scrotal edema Conjunctivitis is common pleural friction rubs have been described Urticaria is rare Such an attack frequently referred to by the Samoan term *mumu* ordinarily subsides in 12 to 24 hr but recurrences are common particularly after strenuous exercise Secondary bacterial infection has been found to play no part in these acute episodes nor is mechanical blockage of lymphatics by the worms responsible for the swellings It is probable that hypersensitivity to the parasite or its products is the underlying mechanism of *mumu* but conclusive evidence on this point is lacking

With repeated exposures infected individuals show palpable thickening of lymphatic channels (often first noted in the spermatic cords) rubbery adenopathy and in a small percentage of cases elephantiasis develops this complication is rare below the age of twenty even in natives of heavily infested areas The chronic stage of the disease is often punctuated by acute bouts of "filarial fever" with chills fever headache tender lymphadenopathy localized areas of erythema and edema and severe muscle pain These are thought to be hypersensitivity reactions induced by release of filarial antigen when adults or microfilariae die or a new infection occurs This concept is supported by the frequent occurrence of filarial fever after institution of chemotherapy and by the fact that an attack can sometimes be produced by intracutaneous injection of the specific antigen in skin testing

Laboratory Findings Eosinophilia accompanies *mumu* in about two thirds of the cases and is also common during attacks of filarial fever in the later stages of the disease Although adult worms are often demonstrable in biopsied lymph nodes this procedure is not often used and excision of nodes often induces a symptomatic flare up of the disease Complement fixation and skin tests are available but neither is reliable in the individual case Diagnosis is best established by demonstration of microfilariae in Giemsa or Wright stains of peripheral blood Microfilariae are motile and can also be found in wet smears When the periodic form of the disease predominates specimens should be collected at night

Treatment The only agent effective against the adult worms is thiacetarsamide (Caparsolate sodium) which is given intravenously as a 1 per cent solution in a dosage of 1 0 mg per kg daily for 15 days Diarrhea sometimes accompanies administration of this drug Although microfilariae may be demonstrable in the blood after a course of thiacetarsamide they soon disappear and relapse is rare

Hetrazan (diethylcarbamazine) in an oral dosage of 2 0 mg per kg t i d for 3 or 4 weeks is an effective microfilaricide The initiation of treatment with this drug may be followed by a bout of filarial fever that usually subsides within 3 days

Antimony compounds no longer have a place in the treatment of filariasis

Other treatment is symptomatic Reassurance of the patient is very important in this disease Vaccines and antiserums are valueless Bandaging and surgery are sometimes beneficial in elephantiasis The prognosis for life is excellent particularly if

studies of diaphragms obtained at autopsy and for biopsy specimens as well

Differential Diagnosis Trichinosis must be distinguished from acute glomerulonephritis typhoid fever meningitis rheumatic fever rheumatoid arthritis eosinophilic leukemia dermatomyositis and periarteritis nodosa

Treatment There is as yet no specific treatment for trichinosis Symptomatic treatment is directed toward the relief of pain maintenance of an adequate caloric and fluid intake and assuring the patient of adequate sleep by use of sedatives ACTH is reported to have controlled the systemic reaction in severe infection and is recommended for such cases However in experimental infections cortisone administration results in more prolonged persistence of the adult worms in the intestine increased numbers of larvae in the musculature and partial suppression of the immune response

Piperazine citrate has been found effective in removing the adults from the intestine in experimental infections It would seem advisable to use piperazine citrate (as prescribed for enterobiasis) during the early phases when adult trichinae are suspected of being in the intestine This would apply when diarrhea and other abdominal symptoms have developed subsequent to the ingestion of undercooked meat and also later when fever and eosinophilia have appeared since treatment may reduce the period of larviposition and thereby shorten the clinical course

Prognosis The prognosis in children is usually better than in adults If there is no serious involvement of the myocardium or respiratory muscles the prognosis is generally good The longer the appearance of symptoms is delayed the better the prognosis Diarrhea early in the course is a favorable sign Analysis of larger series of sporadic and epidemic cases shows the mortality rate to be about 5 per cent

Prevention The responsibility for control rests with the consumer Adequate cooking of pork involves heating all portions of the meat to 55 C Freezing procedures to kill the larvae require a temperature of −15 C for 20 days or −18 C for 24 hr Proper smoking and pickling will also destroy the larvae Important in control is the cooking of garbage fed to hogs There is at present no practical method of inspection which will detect trichinous pork

200 FILARIASIS

Ivan L Bennett Jr

Definition Filariasis is a group of disorders produced by infection with nematodes of the super family Filarioidea These worms invade the subcutaneous tissues and lymphatics of man producing reactions ranging from acute inflammation to chronic scarring The clinical pictures produced by different species in this group are more or less specific The term *filariasis* is commonly used to designate the disease produced by *Wuchereria bancrofti* or *W malayi* the organisms responsible for elephantiasis The disorders associated with infection by *Loa loa* or *Onchocerca volvulus* are usually referred to as *loiasis* and *onchocerciasis*

Filariasis (Wuchereriasis)

Etiology and Epidemiology Adult worms live only in the lymphatics of human beings the male measuring 35 mm and the female 50 to 100 mm Gravid females release microfilariae in large numbers into the lymph and blood These embryos develop further only if ingested by a proper mosquito vector usually *Culex fatigans* although many *Culex Aedes* and *Mansonia* species are good hosts After further development in the vector larvae migrate to the mouth parts and if inoculated into a human host reach maturity in about a year In the absence of reinfection man harbors microfilariae for 5 to 10 years the reproductive life of the adult worms The release of microfilariae into the blood is strikingly

it occurs in the Nile Delta Anglo Egyptian Sudan Zanzibar Madagascar and Central Africa

Schistosoma japonicum affects the population engaged in agriculture In Japan China and the Philippines men are more frequently infected than women An important source of infection in the Orient is the use of human excreta as a fertilizer in vegetable gardens

Schistosoma haematobium is distributed widely throughout the African continent and to a much less extent is found in Spain Portugal Cyprus and Greece In Africa it is highly prevalent among the indigent agricultural population of the Nile Valley

The best attack on schistosomiasis is preventive Public health measures including proper disposal of human excrement and anthelmintic therapy should be carried out in endemic areas Extermination of the mollusk intermediate host by chemical agents in areas where the infestation rate is high is mandatory Sodium pentachlorophenate has been tried against the snails *Australorbis glabratus* and *Oncomelania nosophora* with promising results

Another efficient molluscacide is 2 cyclohexyl 4 6 dinitrophenol

SCHISTOSOMIASIS MANSONI (Intestinal Bilharziasis Schistosomal Dysentery)

Etiology and Life Cycle The male worm measures about 1 cm in length and has a breadth of about 0 13 cm The female is long slender and cylindroid its average length being 1 4 cm and its breadth about 0 016 cm The male has a central trough the gynecophoral canal that enfolds the female during copulation The eggs are bluntly oval have a lateral spine and measure about 140 μ by about 60 μ They are passed in the feces rarely in the urine and can infect only the proper snail which serves as the intermediate host The ova must reach fresh water if the parasite s life cycle is to be completed As stated by Belding the life cycle includes the passing of the ova from the definitive host or man its hatching in water the liberation of a free swimming *miracidium* the penetration of a proper species of snail by the miracidium the metamorphosis of the larvae into *cercariae* (the infective form of the schistosome) their return to water the penetration of the skin of man and finally the migration and growth of the worms in the blood vessels of man and the laying of eggs by the female Adult worms live in the inferior and superior mesenteric veins and the hemorrhoidal plexus

Pathology According to E Koppisch schistosomiasis mansoni is divisible into three stages (1) an early stage of migration during which the cercariae are being carried by the blood to the liver maturing into adult parasites within intrahepatic portal veins (2) an intermediate stage during which ova are accumulating in various viscera and (3) a late stage characterized by serious and permanent damage to organs mainly through fibrosis

The greatest damage to man s tissues is caused by the eggs However the secretions metabolic products and toxins of the adult worms are believed by some to play an important role As long as they are living the adult parasites apparently produce no reaction but when they die numerous eosinophils gather about them

Histologically the predominant lesion is the pseudotubercle—a lesion incited by the ova retained in the tissues

In the colon ulceration is rare and the distal parts are more frequently and seriously involved Congestion of the mucosa punctate hemorrhages and thickening of the wall due to edema and fibrosis of the submucosa are the main findings In Egypt pedunculated or sessile polyps are commonly found in the rectum Changes in the liver are largely portal Ova transported from the colon by venous blood are retained in the portal spaces Pseudotubercles form around them accompanied by eosinophils Grossly the organ is enlarged during the intermediate stage but later contracts as scarring increases On section the characteristic feature is a periportal fibrosis The larger portal veins are surrounded by collars of fibrous tissue constituting the characteristic pipe stem cirrhosis of Symmers The spleen frequently becomes enlarged sometimes weighing more than 1 500 Gm Ova and pseudotubercles in the spleen are more frequently encountered in Egypt than in America In the lungs small grayish nodules averaging 1 mm in diameter are visible or palpable throughout the pulmonary tissue These are made up of pseudotubercles around the eggs that have been carried by the blood In some cases the gross appearance of the lung resembles miliary tuberculosis Microscopically there are pseudotubercles, patches of marked eosinophilic infiltration and occasionally hemorrhages The eggs arriving in the lungs as emboli obstruct the small arteries and the intima becomes thickened by fibrosis In time the right side of the heart undergoes hypertrophy and failure ensues

Manifestations The clinical manifestations of schistosomiasis may be correlated with anatomic changes resulting from the reaction of tissues to the parasites and their ova The finding of schistosome ova in the stools of apparently healthy individuals is a relatively frequent occurrence in endemic areas Unlike the bacterial infections the parasites do not multiply within the human host Thus the symptomatic disease is dependent upon the continued exposure to infection

Itching may or may not occur shortly after exposure and urticaria is variable Mild pyrexia may

infected individuals leave endemic areas or other wise avoid reinfections

Onchocerciasis

This infection is produced by *Onchocerca volvulus* and is transmitted by flies of the genus *Simulium* The disease is widespread in southern Mexico and Guatemala and is common in Central Africa The characteristic lesions of onchocerciasis are subcutaneous nodules that tend to occur in the region of the head although in Africa they are said to be common on the trunk The aspirated contents of the nodules contain adult worms and microfilariae

Treatment consists of surgical excision of the nodules and administration of Hetrazan Except for occasional invasion of the eye the disease has a favorable prognosis unless the number of nodules exceeds 50 in the individual patient

Loiasis

This form of filariasis is produced by *Loa loa* and is prevalent in West and Central Africa The infection is transmitted by flies of the genus *Chrysops* Localized areas of allergic inflammation in the subcutaneous tissues known as *Calabar swellings* are the hallmark of the disease although infestation may be completely asymptomatic The adult worms are sometimes visible beneath the conjunctiva and *Loa loa* is often called the *eye worm* Diagnosis can be made by finding the adult worm or demonstration of microfilariae in contents of Calabar swellings or in blood smears Treatment is symptomatic and the prognosis is good

201 SCHISTOSOMIASIS (Bilharziasis)

Rafael Rodriguez Molina

Definition Schistosomiasis (bilharziasis) is a general term employed to describe a group of disease entities produced in man and animals by three closely related species of digenetic trematodes or blood flukes belonging to the family Schistosomatidae These worms are *Schistosoma mansoni* *S haematobium* and *S japonicum* They inhabit the circulatory system of man and animals living in tropical and subtropical countries The organs and tissues most frequently affected are the colon urinary bladder liver spleen rectum genitalia lungs mesentery and peritoneum

History Bilharz in 1851 first demonstrated the role of *S haematobium* in the prevailing hematuria and dysentery among the native population of Egypt The presence of two types of spined ova and of two clinical forms of the disease the vesical and the intestinal caused confusion until Sambon in 1907 demonstrated the existence of two species *S haematobium* and *S mansoni* The presence of schistosomiasis in Egyptian mummies indicates that it is an ancient disease It was in Puerto Rico in 1904 that the ova of *Schistosoma mansoni* were first discovered among the indigenous population of the Western Hemisphere by Gonzalez Martinez Katsurada in Japan in 1904 found the eggs in the stools of patients affected with Katayama disease Other Japanese investigators demonstrated that dogs cats horses cattle and wild rats were natural hosts or reservoirs of infection

Epidemiology and Control Schistosomiasis is probably the most important of the parasitic diseases affecting man not only because of the extensive pathologic changes produced by the parasites but also because of its world wide distribution and the number of individuals affected With the remarkable control of malaria during recent years the eradication and control of schistosomiasis has become a challenge to the public health officer the sanitary engineer the malacologist the zoologist and the physician

The continuing prevalence of schistosomiasis depends upon the disposal of human excrement into fresh water the presence of suitable snail hosts and the exposure of persons to water infested with cercariae Promiscuous defecation latrine drainage and unsanitary sewage disposal are the more important sources of pollution of streams and rivers The disease is contracted by persons washing clothes bathing wading or working in contaminated water

Schistosomiasis is more frequently encountered in rural than in urban communities and is associated with agricultural endeavors such as the irrigation of land It is more prevalent among low income groups

Of the three disease producing blood flukes of man *S mansoni* is by far the most common in the Western Hemisphere It was brought to the Caribbean area and South America by African slaves In South America Venezuela Dutch Guiana and Brazil are the areas in which it is present In Africa

perience has shown that for a period of about 1 month following administration of either Fuadin or Anthiomaline stool examination and rectal biopsy may give negative results which are misleading It is preferable to give several Fuadin courses (50 to 60 ml) a year if the tolerance of the patient per mits Toxic manifestations occur in 20 to 30 per cent of the patients Pain at the site of the injection and generalized arthralgia are common however hepa titis acute nephritis and thrombocytopenic purpura have been observed Triostam (sodium antimonyl gluconate) has been used with success It is well tolerated and toxic reactions are rare One disad vantage is that the drug must be administered intra venously In the late stages of the disease these therapeutic measures are palliative since the pa tient is suffering from cirrhosis of the liver portal hypertension or hypersplenism The indications for surgical procedures are the same as for the other forms of portal hypertension (p 1507)

Prognosis The prognosis is good in infections where the symptomatology is mainly secondary to colitis but when the liver spleen and lungs are involved the prognosis is poor

SCHISTOSOMIASIS JAPONICA (Eastern Schistosomiasis Katayama Disease)

Etiology and Life Cycle The male worm has an average length of about 1 5 cm and a breadth of 0 05 cm The female is long and slender averaging 1 9 cm in length and 0 03 in breadth The eggs are slightly oval and are shorter wider and distinctly smaller than those of the other two species meas uring about 90 by 70 μ Mature eggs have a minute hook or spine laterally situated and smaller than that of *S mansoni* The ova are passed in the feces only The life cycle is similar to that of *S mansoni* but various species of *Oncomelania* and *Katayama* snails are utilized as intermediate hosts *Schistosoma japonicum* lives in the inferior mesenteric venules but frequently migrates into the venules draining the large intestine and oviposits there

Pathology *Schistosoma japonicum* resembles the mansoni type but because of the much greater number of ova deposited by the female worms in the former disease the manifestations are frequently more severe Cirrhosis of the liver develops earlier and the duration of the disease is shorter—death often ensuing in 2 to 5 years In advanced cases the gross post mortem findings are emaciation and pallor large or contracted liver with periportal fibrosis splenomegaly with fibrosis of pulp ascites fibrotic nodules over the colonic peritoneum fibrous thickening and rigidity of the colon with small polyps projecting from the mucosa and thickening and fibrosis of the omentum Microscopically the tissue changes are similar to those of schistosomiasis mansoni

Manifestations Following penetration of cer cariae through the skin allergic manifestations such as urticaria itching localized dermatitis cough and angioneurotic edema accompanied by fever and diarrhea may appear Four to six weeks after exposure gastrointestinal symptoms are evident a result of ulcerations produced in the intestinal walls by the large number of eggs Bloody mucoid stools or periods of bloody diarrhea accompanied by ab dominal pain may be present If untreated symp toms may last for several months The liver en larges and becomes tender and splenomegaly de velops

As the disease progresses the spleen becomes larger and the size of the liver decreases Signs of portal obstruction such as engorgement of super ficial abdominal veins ascites etc appear The patient may succumb from hemorrhage due to rupture of esophageal varices Some individuals present marked splenomegaly a small contracted liver profound anemia leukopenia and thrombo cytopenia associated with severe malnutrition and hypoproteinemia The majority of individuals suf fering from schistosomiasis japonica die of cirrhosis and cachexia massive hemorrhage from rupture of esophageal varices or intercurrent infections

Diagnosis and Laboratory Findings The charac teristic ova must be found in the stools in order to establish the diagnosis In established cases ova are more difficult to demonstrate in the stools or in rectal biopsy and the intradermal skin test is of value Aqueous extracts of cercariae or of adult worms are employed

Treatment Tartar emetic and Fuadin have been employed in doses somewhat higher than those used in schistosomiasis mansoni In general *S japonicum* infections are more difficult to treat and relapses are more frequent Miracil D (Nilodin lucanthone hydrochloride) a synthetic nonmetallic compound containing a xanthone nucleus has been employed by the oral route It is absorbed rapidly and 60 mg per kilogram daily in divided doses given for a period of 3 to 6 days is the recommended dosage Mild toxic reactions such as abdominal pain weak ness nausea and vomiting have occurred and re sults have not been very successful

Prognosis If the condition is not treated early prognosis is poor in the majority of cases encoun tered in endemic communities

SCHISTOSOMIASIS HAEMATOBIA (Genitourinary Schistosomiasis Endemic Hematuria)

Etiology and Life Cycle The male worm has an average length of 1 3 cm and a breadth of 0 09

accompany urticaria Anorexia headache generalized aches and pains and diarrhea accompanied by abdominal discomfort soon follow and last 1 to 2 weeks These symptoms occur after invasion of the parasite and during the periods of migration of the larvae or cercariae From 30 to 70 days following exposure when the cercariae have become adult males and females and oviposition has occurred more severe symptoms appear In some cases there is high fever (39 to 40 C) with chills and abdominal discomfort Diarrhea and melena are common A persistent dry cough is present and scattered fine or coarse rales can be heard over the chest The peripheral blood shows an eosinophilic leukocytosis and ova are usually found in the stools The findings in the peripheral blood excepted the clinical picture resembles typhoid fever or paratyphoid fever This acute illness usually lasts from 1 to 3 months and subsides by lysis When the initial infection is not severe or when anthelmintic treatment is given the patient may recover rapidly but should the infection remain untreated intermittent bloody diarrhea frequently lasts several months The severity and duration of these symptoms depend upon the extent of the initial infection In untreated cases however several years may pass without signs of visceral disease Should reinfection occur fever and severe gastrointestinal symptoms again ensue Anemia at times severe enough to cause invalidism may be present as the result of chronic blood loss In many cases the liver and the spleen become enlarged

The late stage of the disease frequently gives rise to a new clinical picture The manifestations at this time resemble Banti s syndrome with emaciation hepatosplenomegaly ascites and other evidences of hepatic cirrhosis and portal hypertension Some patients develop leukopenia thrombocytopenia and macrocytic anemia However the bone marrow shows no megaloblastic arrest Liver function tests are frequently abnormal Massive hematemesis from ruptured gastroesophageal varices is a frequent cause of death and hepatic insufficiency is not uncommon In Egypt rectal and colonic polyposis prolapse of the rectum and intestinal obstruction are common late manifestations of the disease

In some patients particularly adolescents in whom irreversible vascular changes have occurred in the lungs pulmonary hypertension associated with chronic cor pulmonale dominate the clinical picture and a form of Ayerza s disease ensues This may overshadow the already present hepatic cirrhosis and portal hypertension

Diagnosis and Laboratory Findings Diagnosis of the condition must be made by finding the ova in the stools in the rectal mucosa or rarely in the urine Various techniques of stool concentration are available and the reader is referred to texts on clinical parasitology for technical details By the use of such methods greater numbers of eggs are picked up from a given specimen and a larger number of cases may be detected The intradermal skin test employing cercaria or worm extract possesses diagnostic value in suspected cases where no ova can be found in the stools or in the rectal biopsy Serodiagnosis particularly the circumoval precipitin reaction shows promising results By means of a Jackson s laryngoscopic forceps 35 cm long a piece of mucosa 2 to 3 mm in diameter can be readily obtained through a proctoscope When this unstained tissue is compressed between two glass slides the ova can be recognized easily under the low power lens of a microscope It is believed by many investigators that rectal biopsy is the most reliable method of diagnosis a very small piece of tissue may contain up to several hundred ova In many cases in which repeated stool examinations have been negative rectal biopsy has shown living or dead ova Occasionally however stools contain ova when biopsy is negative

Bilirubinemia and jaundice are seen rarely even in the presence of advanced cirrhosis

Treatment Certain trivalent antimony compounds have been found effective against *S mansoni* These are tartar emetic (antimony potassium tartrate) stibophen (Fuadin) and Anthiomaline Tartar emetic is one of the more toxic antimony compounds It is administered intravenously in a freshly prepared solution in initial dose of 0 06 Gm increasing to a maximum of 0 12 Gm by the third dose and continued every other day until a total of 2 2 Gm has been given A second course may be given after 1 month Antimony sodium tartrate —less toxic than the potassium salt—is being employed with great success Fuadin is antimony pyrocatechin sodium sulfonate and contains 13 per cent trivalent antimony *It has the advantage of* intramuscular administration It is well tolerated and produces a minimum of toxic reactions when given in courses of not over 50 to 60 ml each Daily injections of 1 5 3 5 and 5 ml are given for the first 3 days to be continued every other day with 5 ml doses until a complete course has been administered The effectiveness of Fuadin as an anthelmintic is believed to be not greater than 50 to 60 per cent Antimony lithium thiomalate (Anthiomaline) is administered intramuscularly in 2 to 3 ml doses every other day until a total of 30 to 40 ml is given comprising one course Lucanthone hydrochloride (Miracil D) has been employed with promising results This drug has the advantage of being active by the oral route

The disappearance of eggs from the stools and improvement in *symptomatology constitute the criteria* for evaluation of anthelmintic therapy Ex

perience has shown that for a period of about 1 month following administration of either Fuadin or Anthiomaline stool examination and rectal biopsy may give negative results which are misleading It is preferable to give several Fuadin courses (50 to 60 ml) a year if the tolerance of the patient permits Toxic manifestations occur in 20 to 30 per cent of the patients Pain at the site of the injection and generalized arthralgia are common however hepatitis acute nephritis and thrombocytopenic purpura have been observed Triostam (sodium antimonyl gluconate) has been used with success It is well tolerated and toxic reactions are rare One disadvantage is that the drug must be administered intravenously In the late stages of the disease these therapeutic measures are palliative since the patient is suffering from cirrhosis of the liver portal hypertension or hypersplenism The indications for surgical procedures are the same as for the other forms of portal hypertension (p 1507)

Prognosis The prognosis is good in infections where the symptomatology is mainly secondary to colitis but when the liver spleen and lungs are involved the prognosis is poor

SCHISTOSOMIASIS JAPONICA (Eastern Schistosomiasis Katayama Disease)

Etiology and Life Cycle The male worm has an average length of about 1 5 cm and a breadth of 0 05 cm The female is long and slender averaging 1 9 cm in length and 0 03 in breadth The eggs are slightly oval and are shorter wider and distinctly smaller than those of the other two species measuring about 90 by 70 μ Mature eggs have a minute hook or spine laterally situated and smaller than that of *S mansoni* The ova are passed in the feces only The life cycle is similar to that of *S mansoni* but various species of *Oncomelania* and *Katayama* snails are utilized as intermediate hosts *Schistosoma japonicum* lives in the inferior mesenteric venules but frequently migrates into the venules draining the large intestine and oviposits there

Pathology *Schistosoma japonicum* resembles the mansoni type but because of the much greater number of ova deposited by the female worms in the former disease the manifestations are frequently more severe Cirrhosis of the liver develops earlier and the duration of the disease is shorter—death often ensuing in 2 to 5 years In advanced cases the gross post mortem findings are emaciation and pallor large or contracted liver with periportal fibrosis splenomegaly with fibrosis of pulp ascites fibrotic nodules over the colonic peritoneum fibrous thickening and rigidity of the colon with small polyps projecting from the mucosa and thickening and fibrosis of the omentum Microscopically the tissue changes are similar to those of schistosomiasis mansoni

Manifestations Following penetration of cercariae through the skin allergic manifestations such as urticaria itching localized dermatitis cough and angioneurotic edema accompanied by fever and diarrhea may appear Four to six weeks after exposure gastrointestinal symptoms are evident a result of ulcerations produced in the intestinal walls by the large number of eggs Bloody mucoid stools or periods of bloody diarrhea accompanied by abdominal pain may be present If untreated symptoms may last for several months The liver enlarges and becomes tender and splenomegaly develops

As the disease progresses the spleen becomes larger and the size of the liver decreases Signs of portal obstruction such as engorgement of superficial abdominal veins ascites etc appear The patient may succumb from hemorrhage due to rupture of esophageal varices Some individuals present marked splenomegaly a small contracted liver profound anemia leukopenia and thrombocytopenia associated with severe malnutrition and hypoproteinemia The majority of individuals suffering from schistosomiasis japonica die of cirrhosis and cachexia massive hemorrhage from rupture of esophageal varices or intercurrent infections

Diagnosis and Laboratory Findings The characteristic ova must be found in the stools in order to establish the diagnosis In established cases ova are more difficult to demonstrate in the stools or in rectal biopsy and the intradermal skin test is of value Aqueous extracts of cercariae or of adult worms are employed

Treatment Tartar emetic and Fuadin have been employed in doses somewhat higher than those used in schistosomiasis mansoni In general *S japonicum* infections are more difficult to treat and relapses are more frequent *Miracil D* (*Nilodin lucanthone hydrochloride*) a synthetic nonmetallic compound containing a xanthone nucleus has been employed by the oral route It is absorbed rapidly and 60 mg per kilogram daily in divided doses given for a period of 3 to 6 days is the recommended dosage Mild toxic reactions such as abdominal pain weakness nausea and vomiting have occurred and results have not been very successful

Prognosis If the condition is not treated early prognosis is poor in the majority of cases encountered in endemic communities

SCHISTOSOMIASIS HAEMATOBIA (Genitourinary Schistosomiasis Endemic Hematuria)

Etiology and Life Cycle The male worm has an average length of 1 3 cm and a breadth of 0 09

cm The female is long and slender averaging 2 0 cm in length and 0 025 cm in breadth The eggs are compact elongated spindles dilated in the middle and measuring about 140 μ by about 50 μ At one pole they present a short stout terminal spine The ova are passed in the urine and occasionally in the feces The life cycle is similar to that of S *mansoni* The adult worms live in the hemorrhoidal plexus of veins some going to the rectum for oviposition but most of them passing on to the vesical plexus The intermediate hosts are snails of the genera *Bulinus Physopsis* and *Lymnaea*

Pathology In the urinary bladder large numbers of ova are deposited in the submucosa and give rise to dense infiltration with eosinophils lymphocytes and plasma cells These foci or pseudoabscesses" apparently represent an allergic reaction to the eggs but even though many of the eosinophils undergo necrosis and fragmentation the lesion is not a true abscess The mucosa becomes thickened and ulcerated The trigone is involved at first but soon the entire bladder is affected In chronic infections the other coats become scarred and the muscularis hypertrophies Pedunculated papillomas often develop at the trigone and about the urethral orifices The bladder capacity becomes greatly reduced as the organ loses its contractility Lesions occur in the distal third of the ureters in many cases causing obstruction and hydronephrosis In about 10 per cent of cases calculi develop in the bladder renal pelvis or ureters Fistulas between the urogenital tract and intestines may develop The prostate and seminal vesicles may be affected and lymph blockage may produce an elephantoid condition of the genitalia The cervix and vagina can be infected by extension from the bladder Carcinoma of the bladder is a frequent late complication

Manifestations Painful micturition frequency and hematuria are the leading symptoms Secondary bacterial infection of the urinary tract is frequent and repeated hemorrhages from the bladder produce severe anemia

Diagnosis and Laboratory Findings As in the other types of schistosomiasis diagnosis is made by finding the characteristic ova in the urinary sediment in tissues obtained from vesical mucosa or less frequently in the stools

Treatment Chemotherapy is effective early in the disease but is contraindicated when urinary obstruction and infection have supervened Lucanthone hydrochloride (Miracil D) appears to be more efficient (80 to 85 per cent) than Fuadin and nearly as effective as intensive treatment with intravenous antimony sodium tartrate Triostam (sodium antimonyl gluconate) has been found to be effective against infection with S *haematobium* Surgery may be required for abscesses fistulas strictures papillomas and various other complications involving the bladder The criteria of cure are the absence of ova in the urine and bladder wall and the disappearance of ulcerative and granulomatous lesions as revealed by cystoscopic examination

Prognosis Provided treatment is given early prognosis is good in recent infection fair when damage to the bladder and urinary infection have already occurred and very poor in chronic late infections After age forty five the mortality rate increases fourfold The frequent coexistence of infection with S *mansoni* aggravates prognosis and the clinical picture

SCHISTOSOME DERMATITIS

Definition and Geographic Distributions Cort demonstrated that certain nonhuman schistosome cercariae may penetrate the skin of man and cause a dermatitis This condition is known as *schistosome dermatitis* or swimmer s itch" and is common in many parts of the world The condition apparently does not develop after a single contact with cercariae but it ensues following multiple exposures Definitive hosts of some of the schistosomes producing dermatitis are the muskrat and migratory birds Again snails are intermediate hosts

Schistosome dermatitis has been reported from the fresh water areas of north central United States Canada Oregon Central America Western Europe (particularly Switzerland) and the Far East

A sea water dermatitis believed to be produced by nonhuman schistosome cercariae has been reported in New York Rhode Island California, Hawaii and Florida

Pathogenesis and Clinical Manifestations Because the dermatitis develops only after multiple exposures the condition is believed to represent an allergic reaction the nonhuman cercariae being the sensitizing agents Exposed individuals show positive intradermal reaction when tested with cercarial antigen

Treatment Local application of antipruritic lotions such as calamine with menthol or phenol is used to allay itching and thereby to reduce the likelihood of secondary infection Local treatment with antihistaminic drugs will relieve the pruritus

Prevention Immediate drying of the skin after swimming has been recommended as a prophylactic measure This will not completely prevent lesions since some penetration occurs during immersion Dimethyl phthalate cream has been reported as an effective cercarial repellent

In some areas control has been effected by destruction of snails Copper sulfate and copper car

bonate have been used for this purpose Treatment of shallow waters where snails are abundant has been moderately effective

Paragonimiasis

Paragonimiasis also known as *endemic hemoptysis* is an infection, primarily of the lung caused by *Paragonimus westermani* In addition to man also the dog cat, pig rat and some wild carnivores serve as definitive hosts The characteristic cystlike pulmonary lesions measure up to about 1 cm in diameter and when of long standing have a stout wall composed of fibrous connective tissue Other smaller lesions may be in the form of nodules representing reaction around deposited eggs Eggs appear in the feces when sputum from pulmonary lesions is swallowed In heavy infections lesions may also be found in the liver mesentery skeletal muscle and brain According to the sites of predominant involvement, cases may be classified as pulmonary abdominal or cerebral *In the pulmonary type* abundant brownish sputum is produced and bouts of hemoptysis occur Abdominal pain and dysentery characterize the abdominal type Various types of paralysis and epilepsy are observed with cerebral involvement Eosinophilia is rather constant in all varieties of paragonimiasis Eggs should be searched for in the sputum and feces in attempting to establish the diagnosis By using an antigen prepared from the adult trematodes complement fixing antibodies can be demonstrated This may be helpful in identifying occult abdominal and cerebral infections

Treatment with emetine hydrochloride as prescribed for fascioliasis affords symptomatic relief However there is no specific effective therapeutic agent Prevention of superimposed infections is important, since the infection is in a sense self limiting

Paragonimiasis has probably the widest geographic distribution of any of the diseases produced by *the hermaphroditic trematodes It is endemic* in many parts of the Far East and has been reported from parts of Africa and northern South America

The most practicable control measure is the adequate cooking of all shellfish to be used as food, since infection is acquired by ingestion of cysts in the second intermediate host, such as a crab crayfish or mollusk.

Clonorchiasis

Definition. Clonorchiasis is an infection caused by *Clonorchis sinensis* and is characterized by *hepatic lesions produced by the adult worms in the biliary passages*

Etiology *Clonorchis sinensis* the most important liver fluke in man is a hermaphroditic worm measuring about 15 mm by 5 mm Infection of man follows on ingestion of raw fish containing the larval *Clonorchis* Many fish-eating mammals can serve as definitive hosts (dog, cat, pig, badger guinea pig, and others) The encysted larva is released and migrates from the duodenum into the

biliary tract where it develops into the adult form Judging from studies on individuals who have left the Far East the major endemic area the adult *Clonorchis* is capable of living as long as twenty five years

Clinical Manifestations The percentage of asymptomatic infections is probably high The bile ducts become thickened and dilated and there is chronic pericholangitis and atrophy of parenchyma but cirrhosis with the usual clinical manifestations is uncommon

Laboratory Diagnosis The diagnosis usually depends on the demonstration of the eggs in the feces or the duodenal contents

Treatment No method of treatment has been consistently successful but some success has been noted with gentian violet and chloroquine diphosphate Gentian violet may be given as for strongyloidiasis Chloroquine is prescribed in a dose of 0 25 Gm twice daily for 28 days Most infections will respond to this dosage those which do not should be treated for an additional 2 to 3 week period

Prevention Adequate cooking of fresh water fish will prevent infection

Opisthorchiasis

Opisthorchiasis is caused by *Opisthorchis felineus* and is characterized by hepatic lesions occasioned by the presence of the adult worms in the larger bile ducts The life cycle resembles that of *Clonorchis sinensis* with lesions and clinical manifestations like those produced by *C sinensis* The geographic distribution differs in that it is endemic in Eastern and Central Europe and in Siberia and occurs in some parts of Asia The diagnosis usually is based on the finding of the eggs in the feces or duodenal contents Treatment as recommended for clonorchiasis may be used Infection can be prevented by eating only well cooked fish

Fascioliasis

Fascioliasis is caused by the hermaphroditic leaf shaped fluke *Fasciola hepatica* which inhabits the bile ducts of the definitive host When fully matured the adult measures about 3 cm by 1 cm and discharges large operculate eggs 140 mm by 70 mm

Fascioliasis produces so called "liver rot in the sheep the principal definitive host The disease is most common in sheep and cattle raising countries but has been reported from many parts of the world On the North American continent it occurs in the southern and western United States Central America and in the Caribbean islands

Infection is contracted by ingestion of the encysted form attached to edible aquatic plants such as water cress

Early clinical manifestations are related to the migration of the larval form to and within the liver Epigastric pain fever diarrhea jaundice urticaria pruritis arthralgia and eosinophilia may be observed during this stage Cirrhosis of the liver of the variety found in clonorchiasis may be a late manifestation appearing only after prolonged residence of many adult worms in the bile ducts A pharyngeal form of the disease may follow on the ingestion of infected raw liver the young adults attaching themselves to the pharyngeal mucosa occasionally interfering with respiration

The diagnosis usually is based on the finding of the eggs in the feces or in the duodenal contents It is difficult to distinguish the eggs from those of *Fasciolopsis buski*

The therapeutic agent by choice is emetine hydrochloride given intramuscularly The dose should not exceed 1 mg per kilogram body weight or a total daily dose of 60 mg in these amounts it should not be given for more than 6 to 7 days Thirty milligrams per day has been given for as long as 18 days with good results It should be given only when there is ample opportunity for rest in bed It should not be given to patients with chronic cardiac or renal disease or to children

To prevent infection in man aquatic plants such as water cress should not be eaten vegetables grown in fields irrigated with polluted water should be boiled and safe drinking water should be provided

Fasciolopsiasis

Fasciolopsiasis is caused by the large intestinal fluke *Fasciolopsis buski* which inhabits the upper intestine of its definitive host The principal definitive host is the pig In parts of China India and other parts of the Far East infection of man is common Infection is contracted following ingestion or peeling with the teeth of water chestnuts and other edible aquatic plants The large adults attach themselves to the intestinal mucosa and these sites may later ulcerate Diarrhea and abdominal pain appear early Later if heavy infection continues asthenia with ascites and anasarca occurs Diagnosis is based upon the history and the finding of eggs in the feces The eggs resemble those of *Fasciola hepatica* The prognosis in untreated heavy infections especially in children is poor Hexylresorcinol administered as for trichuriasis is the preferred therapeutic agent and can be expected to cure or markedly reduce the worm burden in the majority of cases The most practicable control measure is the brief immersion of all edible aquatic plants in boiling water

203 CESTODES OR TAPEWORMS

Gustave J Dammin

Diphyllobothrium Latum

Definition *Diphyllobothrium latum* the fish tapeworm or broad tapeworm produces in man and its other definitive hosts infection characterized by the presence of the hermaphroditic adult worm in the intestinal lumen

Etiology The adult worm may measure from 5 to 10 m and possess between 3 000 and 4 000 proglottids (Fig 151) The mature proglottids measure about 3 to 5 mm in length and 10 to 15 mm in width The stage in the infected fresh water fish the host from which man acquires infection is known as the *plerocercoid larva* or *Sparganum* It is found in large numbers in the muscles and other tissues of the fish

Pathogenesis Ingestion of infected fish in the uncooked state by man the dog the cat or the bear results in infection The larva develops into the adult form in the intestine in about 3 weeks and is then capable of discharging eggs The adults

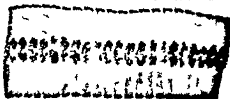

Fig 151 Gravid proglottids of *Diphyllobothrium latum* (×2)

of *D latum* have been known to survive for periods of 5 to 10 years

Distribution Fish tapeworm infection is common in the Baltic and Scandinavian countries Switzerland Italy Russia, Japan Chile and Central Africa. It has also been established in the north central United States, south central Canada and Florida

Clinical Manifestations Most infections either are asymptomatic or produce slight transient abdominal discomfort Infrequently severe cramping abdominal pain vomiting weakness and loss of weight are noted

Pernicious tapeworm anemia with erythrocyte counts ranging from half a million to two million has many features in common with Addisonian pernicious anemia, including central nervous system involvement It differs from the latter in that patients produce intrinsic factor but do not respond when given beef extract (extrinsic factor) and normal gastric juice (intrinsic factor) while the tapeworm is still present. Removal of the tapeworm and the administration of extrinsic factor leads to clinical and hematologic improvement The position of the tapeworm in the intestine is important anemia occurring only when the tapeworm is in the proximal small intestine Large amounts of vitamin B_{12} have been demonstrated in the tapeworm presumably absorbed from the host's intestine *Taenia saginata* which does not produce pernicious tapeworm anemia contains about 2 per cent as much vitamin B_{12} as *D latum* The appearance of pernicious tapeworm anemia is related to vitamin B_{12} absorption and possibly also to a decreased production of intrinsic factor and decreased supply of extrinsic factor It is apparent, however that the tapeworm and the host compete for vitamin B_{12} There may be ethnic and geographic factors involved since most cases are reported from the Baltic countries none to date has been reported in this country

Treatment. Atabrine has supplanted oleoresin of aspidium and carbon tetrachloride If prescribed as for taeniasis saginata, Atabrine can be expected to cure most infections In the presence of severe macrocytic anemia, an adequate response to parenteral vitamin B_{12} should be obtained before an anthelmintic is used

Prevention The most practical control measure is the thorough cooking of all fresh water fish Children should not be permitted access to fish markets or to kitchens when fresh water fish is being prepared because of the possibility that some larvae may be ingested To reduce contamination of waterways dogs and cats should not be fed raw fresh water fish

Sparganosis

The *Sparganum* or plerocercoid larva of *Diphyllobothrium mansoni* will develop in man following ingestion usually in drinking water of a *Cyclops* bearing the procercoid larva Sparganosis also follows application of infected fresh frog flesh used as a poultice The frog tissues contain the *Sparganum which is capable of invading human tissues* The dog and cat are definitive hosts for *D mansoni* The location of the larvae determines the prognosis of the infection in man Surgery and local alcohol injection are the only methods of treatment

Sparganum proliferum the adult stage of which is unknown produces a more severe infection because of its unusual multiplication in the human host Nodules containing the larvae form in the skin lungs intestine brain and other sites The prognosis is poor in severe infections

Sparganum mansonoides probably accounts for most of the cases of sparganosis observed in the United States

Taeniasis Saginata

Definition *Taenia saginata* the beef tapeworm is a hermaphroditic cestode which inhabits the intestinal tract of man its only definitive host

Etiology and Pathogenesis In its adult stage the *T saginata* measures from 5 to 10 m in length and possesses about a thousand proglottids The gravid proglottid (Fig 152) measures about 5 mm in width and 20 mm in length It possesses 15 to 30 lateral uterine branches thus distinguishing it from *T solium* which has 8 to 12 The proglottids may show independent motion for long periods after discharge with the feces The head or scolex measures 1 to 2 mm in diameter and possesses prominent suckers but no hooks The eggs are ovoid 30 μ by 40 μ and are indistinguishable from those of *T solium* When the eggs are ingested by cattle the embryo is released in the intestine invades the intestinal wall and is carried by vascular channels to striated muscle in the hind limbs diaphragm and tongue the common sites for formation of the cysticercus stage (*Cysticercus bovis*) *C bovis* measure about 5 mm by 10 mm and consists of a scolex held in a cystlike structure When *C bovis* is ingested in raw or undercooked beef by man the adult tapeworm develops in the intestine in about 2 months

Distribution Taeniasis saginata occurs in countries in which it is the custom to eat raw or undercooked beef It has been estimated that in the USSR alone there are about eighteen million infections and in the world s population almost forty million Although not common in the United States beef tapeworm infection is the most prevalent tapeworm infection observed in the northern half of this country

Clinical Manifestations Symptoms usually consist of mild epigastric pain diarrhea hunger sensations weight loss irritability nausea and rarely an increase in appetite Movements of the worm may be apparent to the host Rarely segments may become impacted in the vermiform appendix with almost simultaneous development of appendicitis *Approximately one fourth of the infections are* asymptomatic

Laboratory Findings The diagnosis is usually made by the finding of proglottids in the feces When the history suggests that proglottids may have been passed but none are immediately available for examination the perianal region should be examined as for pinworm infection using the Scotch tape swab By this method 85 to 95 per cent of infections may be detected whereas by stool examination only 50 to 75 per cent can be recognized When the scolex is obtained it may be examined for suckers and the absence of rostellum and hooks to identify it as *T saginata* The above study is necessary since the ova observed in the feces cannot be distinguished from those of *T solium* A slight eosinophilia may accompany this infection

Treatment Carbon tetrachloride and aspidium oleoresin have long been accepted as efficacious but their occasional toxicity has stimulated search for other agents

Experience with Atabrine has shown it to be a highly efficacious agent which has the advantage of ease of administration The evening before the Atabrine is to be administered the patient takes 30 Gm of sodium sulfate in a glass of water The following morning while still fasting he takes 1 Gm Atabrine followed with a glass of water in which 1 teaspoonful of sodium bicarbonate has been dissolved Two hours later a second dose of sodium sulfate similar to the first is taken When successful such treatment will remove the entire worm which will be found to be stained yellow If the scolex has not been removed regeneration of the tapeworm will occur and retreatment may be necessary in 2 to 3 months

Incomplete removal by Atabrine has been followed by complete removal of the tapeworm subsequent to the administration of Benadryl in Emplet form

Prevention The only practical means of preventing infection is the thorough cooking of beef Tem

peratures as low as 71 C for as little as 5 minutes will destroy *C bovis* Refrigeration and salting for prolonged periods also destroy the *Cysticercus* Adequate meat inspection and disposal of human excreta will also aid in control but are costly and seldom practical

Taeniasis Solium

Definition *Taenia solium* the pork tapeworm usually manifests itself as a parasite of man by inhabiting the intestinal lumen Man is the only definitive host but under some circumstances may act also as the intermediate host harboring the larval stage *Cysticercus cellulosae* The usual intermediate host is the hog

Distribution Taeniasis solium has a world wide distribution but is commonest in the USSR Asia and Africa

Etiology and Pathogenesis The hermaphroditic adult tapeworm measures about 3 m in length and possesses a globular scolex containing a rostellum with about two dozen hooklets There are seldom more than a thousand proglottids The gravid proglottid measures about 6 mm in width and 12 mm in length and contains a uterus with 8 to 12 lateral branchings The eggs resemble those of *T saginata* When ingested by the hog the embryo is released from the egg penetrates the intestinal wall and is carried by vascular channels to all parts of the body Localization with development to the encysted larval stage *C cellulosae* (bladder worm) occurs predominantly in striated muscle particularly that of the tongue neck and girdle muscles The cysticerci are ovoid gray white opalescent structures measuring about 1 cm in diameter An opaque white spot denotes the site of the scolex Man becomes infected following ingestion of undercooked pork containing cysticerci The scolex is freed and attaches itself to the intestinal mucosa and development to the adult stage begins at this time

Clinical Manifestations Clinical manifestations related to the presence of the adult tapeworm resemble those associated with *T saginata* The manifestations differ when man serves as the intermediate host This may occur following ingestion of the eggs or the return of gravid segments to the stomach by reverse peristalsis The released embryo bores into the intestinal wall and is distributed by vascular channels to various parts of the body Cysticerci develop in the subcutaneous tissues in muscles in viscera and—of most significance—in the eye and brain Only moderate tissue reaction occurs while the scolex is viable The dead larva however behaves like a foreign body and provokes a marked tissue response Symptoms are related to active larval encystment only in heavy infections Muscular pains weakness and slight fever may be observed The involvement in the brain may be in

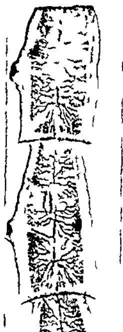

Fig 152 Gravid proglottids of *Taenia saginata* (×2)

the form of a meningoencephalitis when the cysticerci are widely distributed However epilepsy brain tumor encephalitis and other types of neurologic disorder may be simulated Eosinophilic leukocytosis of the blood and spinal fluid accompanying such clinical manifestations suggests cerebral cysticercosis Degenerate cysticerci ultimately calcify

As in other tapeworm infections a slight to moderate eosinophilia is a fairly constant finding The finding of eggs in perianal scrapings or in the feces will identify the infection as taeniasis For a specific diagnosis proglottids or the scolex must be examined As in beef tapeworm infection the diagnosis is usually made by finding proglottids in the feces Roentgenographic demonstration of calcified foci may aid in diagnosis of cysticercosis The prognosis is in large part determined by the stage and location of the parasite Surgery may be indicated in cerebral and ocular cysticercosis

Treatment For removal of the worm in the adult stage see p 1138

Prevention The simplest and most effective preventive measure is the thorough cooking of pork Treatment of recognized cases will reduce the hazard of larval stage development as well as the spread of the infection

Echinococciasis

Definition Echinococciasis may be caused by the larval stage of *Echinococcus granulosus* or *E multilocularis* These species of echinococcus are distinct morphologically and biologically In man

Prevention The most practical control measure is the thorough cooking of all fresh water fish Children should not be permitted access to fish markets or to kitchens when fresh water fish is being prepared because of the possibility that some larvae may be ingested To reduce contamination of waterways dogs and cats should not be fed raw fresh water fish

Sparganosis

The *Sparganum* or plerocercoid larva of *Diphyllobothrium mansoni* will develop in man following ingestion usually in drinking water of a *Cyclops* bearing the procercoid larva Sparganosis also follows application of infected fresh frog flesh used as a poultice The frog tissues contain the *Sparganum* which is capable of invading human tissues The dog and cat are definitive hosts for *D mansoni* The location of the larvae determines the prognosis of the infection in man Surgery and local alcohol injection are the only methods of treatment

Sparganum proliferum the adult stage of which is unknown produces a more severe infection because of its unusual multiplication in the human host Nodules containing the larvae form in the skin lungs intestine brain and other sites The prognosis is poor in severe infections

Sparganum mansonoides probably accounts for most of the cases of sparganosis observed in the United States

Taeniasis Saginata

Definition *Taenia saginata* the beef tapeworm is a hermaphroditic cestode which inhabits the intestinal tract of man its only definitive host

Etiology and Pathogenesis In its adult stage the *T saginata* measures from 5 to 10 m in length and possesses about a thousand proglottids The gravid proglottid (Fig 152) measures about 5 mm in width and 20 mm in length It possesses 15 to 30 lateral uterine branches thus distinguishing it from *T solium* which has 8 to 12 The proglottids may show independent motion for long periods after discharge with the feces The head or scolex measures 1 to 2 mm in diameter and possesses prominent suckers but no hooks The eggs are ovoid 30 μ by 40 μ and are indistinguishable from those of *T solium* When the eggs are ingested by cattle the embryo is released in the intestine invades the intestinal wall and is carried by vascular channels to striated muscle in the hind limbs diaphragm and tongue the common sites for formation of the cysticercus stage (*Cysticercus bovis*) *C bovis* measures about 5 mm by 10 mm and consists of a scolex held in a cystlike structure When *C bovis* is ingested in raw or undercooked beef by man the adult tapeworm develops in the intestine in about 2 months

Distribution Taeniasis saginata occurs in countries in which it is the custom to eat raw or undercooked beef It has been estimated that in the USSR alone there are about eighteen million infections and in the world s population almost forty million Although not common in the United States beef tapeworm infection is the most prevalent tapeworm infection observed in the northern half of this country

Clinical Manifestations Symptoms usually consist of mild epigastric pain diarrhea hunger sensations weight loss irritability nausea and rarely an increase in appetite Movements of the worm may be apparent to the host Rarely segments may become impacted in the vermiform appendix with almost simultaneous development of appendicitis Approximately one fourth of the infections are asymptomatic

Laboratory Findings The diagnosis is usually made by the finding of proglottids in the feces When the history suggests that proglottids may have been passed but none are immediately available for examination the perianal region should be examined as for pinworm infection using the Scotch tape swab By this method 85 to 95 per cent of infections may be detected whereas by stool examination only 50 to 75 per cent can be recognized When the scolex is obtained it may be examined for suckers and the absence of rostellum and hooks to identify it as *T saginata* The above study is necessary since the ova observed in the feces can not be distinguished from those of *T solium* A slight eosinophilia may accompany this infection

Treatment Carbon tetrachloride and aspidium oleoresin have long been accepted as efficacious but their occasional toxicity has stimulated search for other agents

Experience with Atabrine has shown it to be a highly efficacious agent which has the advantage of ease of administration The evening before the Atabrine is to be administered the patient takes 30 Gm of sodium sulfate in a glass of water The following morning while still fasting he takes 1 Gm Atabrine followed with a glass of water in which 1 teaspoonful of sodium bicarbonate has been dissolved Two hours later a second dose of sodium sulfate similar to the first is taken When successful such treatment will remove the entire worm which will be found to be stained yellow If the scolex has not been removed regeneration of the tapeworm will occur and retreatment may be necessary in 2 to 3 months

Incomplete removal by Atabrine has been followed by complete removal of the tapeworm subsequent to the administration of Benadryl in Emplet form

Prevention The only practical means of preventing infection is the thorough cooking of beef Tem

Fig 153 Daughter cysts occur frequently in large old unilocular hydatid cysts They are thin walled balloons formed by herniations of the wall of the mother cyst and lie free in the cyst fluid Free hooklets are also found floating in this fluid (*Ash and Spitz Pathology of Tropical Diseases Philadelphia W B Saunders Company*)

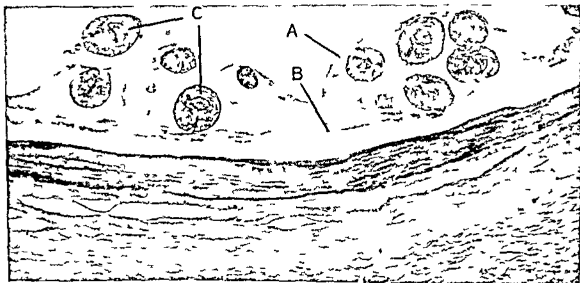

Fig 154 Brood capsules are vesicles of single cell layer (*A*) which arise from the germinal membrane (*B*) Invaginated scolices (*C*) arise as buds from the inner surface of the brood capsule (*Ash and Spitz "Pathology of Tropical Diseases Philadelphia W B Saunders Company*)

E granulosus produces cystic expanding lesions involving the liver and lungs primarily whereas the lesions of *E multilocularis* are destructive because of their invasive character

Etiology *Echinococcus granulosus* infection in man cattle sheep horses and hogs the principal intermediate hosts is contracted by ingestion of the eggs present in the feces of the dog the principal definitive host Following ingestion the embryos escape from the eggs penetrate the intestinal mucosa and enter venous and lymphatic channels Some soon arrive in the liver and may form hydatid cysts there and those entering the lymphatics are carried ultimately to the lungs There is no exogenous budding from the wall of the cyst only endogenous Transmission to the definitive host occurs following ingestion of the hydatid cysts which contain scolices An adult worm may develop from each scolex in the intestine of the dog wolf coyote and other of the Canidae The adult is small measuring about 5 mm in length and consists of no more than 5 or 6 segments *Echinococcus multilocularis* infection is manifested by the same type of invasive larval produced lesion as is observed in the natural intermediate host for this stage the microtine rodents The adult or tapeworm stage is found in the dog and fox

Distribution Echinococciasis caused by *E granulosus* has its highest incidence in sheep and cattle raising countries particularly in North and South Africa Australia Central Europe and South America In Iceland a high incidence of infection in man and the dog has been markedly reduced by control measures In the southern western and southwestern areas of the United States the infection is established and a small number of cases reported each year *Echinococcus multilocularis* has been identified in Eurasia Alaska and the Kuriles and adjacent islands

Pathogenesis and Clinical Manifestations Two principal types of lesions develop in the intermediate host the unilocular type of *E granulosus* and the alveolar type of *E multilocularis* The former is more common grows slowly and consists of an external laminated cuticula and an inner germinal layer Fluid fills and distends the cyst Daughter cysts (Fig 153) and brood capsules (Fig 154) develop from the germinal layer representing endogenous development Hydatid sand found in the cyst consists of scolices liberated from ruptured brood capsules Exogenous development results from evagination of the cyst wall and ultimately produces the multilocular or alveolar type of lesion Metastatic lesions occur when growth extends into vessels

Symptoms produced depend upon the size attained by the cystic lesion and the amount of tissue destroyed Unilocular lesions may become barren following resolution of secondary bacterial infection Rupture into the peritoneal or pleural cavities may produce an anaphylactoid reaction which occasionally is fatal The unilocular type of hepatic lesion progresses slowly and is most amenable to surgical treatment The alveolar type progresses more rapidly with metastatic lesions developing in the bones brain and other sites Pathologic fractures occur and cerebral involvement may be manifested by epilepsy

Diagnosis and Treatment Clinical manifestations seldom are characteristic enough to suggest the diagnosis but roentgenographic appearance of the lesion especially when calcification is present is often helpful (Schlanger and Schlanger) Eosinophilia is suggestive although seldom present Inquiry should be made concerning residence in an endemic area and skin (Casoni or substitute antigen) and/or serologic tests performed before exploration is considered Exploration may be required as both a diagnostic and a therapeutic measure Because of serious reactions to the leakage of cyst fluid into the tissues and body cavities aspiration should be attempted only during exploration Aspirated cyst fluid should be examined carefully for scolices hooklets and laminated cyst wall The size of the lesion will determine whether excision or marsupialization is the procedure of choice Only surgical treatment offers hope of cure

Prevention In prevention (1) contact with infected dogs should be avoided particularly fecal contamination of the hands and food (2) infected carcasses and offal should be burned or buried in order to prevent access of dogs to material containing scolices and (3) dogs should be treated if found to be infected The reduction of the incidence of echinococciasis in Iceland is an example of the efficacy of control measures

Hymenolepiasis Nana

Definition Hymenolepiasis nana is an intestinal infection of man caused by *Hymenolepis nana* the dwarf tapeworm

Etiology The life cycle is unique in that both the larval and adult phases of development occur in the same host Man mice and rats readily contract infection upon ingestion of the eggs The adult measures about 2 cm in length and may possess over a hundred proglottids

Distribution The presence of dwarf tapeworm infection has been reported in temperate and tropical regions around the globe It is the commonest tapeworm found in the United States most of the infections occurring in the Southern states

Clinical Manifestations This tapeworm infection is characterized by the presence of many adult worms in the host's intestine When infection is massive diarrhea and abdominal pain occur

forward thrust of the head and the instant that the erect fangs make contact venom is expressed by sudden muscular contraction

The rattlesnakes recognized by the horny rattle on the tail which buzzes when the snake is disturbed are widely distributed The diamondbacks (*Crotalus adamanteus* in the Southeast and *C atrox* in the Southwest) are the largest and most dangerous snakes in this country Others include the prairie rattler (*C confluentus*) the timber rattler (*C horridus*) and the pigmy rattlers

The water moccasin or cottonmouth (*Agkistrodon piscivorus*) is found in swampy areas or along the banks of streams It is a strong swimmer and can bite under water This snake is notorious for inflicting severe facial bites when disturbed in the branches of small trees The copperhead or highland moccasin (*A mokasen*) is a closely related species Its bite is painful but rarely fatal

Pathogenesis *Snake Venoms* The venoms of many species have been analyzed invariably each proves to be a mixture of several toxic proteins and enzymes As an example the venom of the Indian cobra (*Naja naja*) contains these distinct and separate substances a neurotoxin a hemolysin a cardiotoxin a cholinesterase at least three phosphatases a nucleotidase and a potent inhibitor of cytochrome oxidase Several venoms including those of the pit vipers contain hyaluronidase and numerous proteolytic enzymes Although experts differ about the exact role of these components in toxicity the action of the venom of a given species is usually predominantly neurotoxic or necrotizing frequently associated changes are hemolysis and changes in blood coagulation The venom of elapids including the coral snake is neurotoxic and death results from respiratory paralysis probably caused by damage to brain centers and a curariform interference with transmission at the neuromuscular junction The venom of crotalid snakes produces local tissue injury hemorrhage and hemolysis death is preceded by circulatory collapse the mechanism of which is poorly understood Systemic absorption of venom occurs through lymphatics and therapeutic measures designed to reduce lymphatic function are helpful in controlling symptoms On rare occasions when venom is discharged directly into a blood vessel death occurs in less than 10 min

Factors Affecting Severity Several factors affect the outcome of snake bite

1 The age size and health of the patient Envenomation in children is usually serious and a fatal outcome more likely

2 Bites on extremities or into adipose tissues are less dangerous than those on the trunk or face or penetrating a vessel A direct stroke of the fangs is more dangerous than a scratch a glancing blow or one hitting a bone The discharge orifice of the fang is well above its tip and the point of the fang can penetrate the skin without envenomation Even a thin layer of clothing may afford great protection

3 The size of the snake the extent of its anger or fear (if hurt it may inject a large dose of venom) the condition of the venom glands (recently discharged or full) and the condition of the fangs (broken recently renewed) are all important

4 The presence of various bacteria in the mouth of the snake or on the skin of the victim (especially clostridia) may lead to serious infection in the necrotic tissues at the local site

5 Exercise or exertion such as running immediately after the bite speeds systemic absorption of toxin

Manifestations The bite of a pit viper produces severe pain at the local site within a few minutes There is rapid swelling ecchymoses and bullae appear over the involved areas and as the edema spreads serosanguinous fluid oozes from the puncture wounds Systemic effects include circulatory collapse with hypotension clammy skin tachycardia intense thirst nausea hematemesis bloody diarrhea icterus (rarely intense) hemorrhages from the nose and into the skin and convulsions Death may occur after 6 to 48 hr Survival may be attended by massive local tissue loss from gangrene and secondary infection amputation of an extremity is sometimes necessary Fever of 101 to 104 F polymorphonuclear leukocytosis of 20 000 to 30 000 and albuminuria appear within a few hours in severe cases

The bite of an elapine snake causes little pain and local swelling is slight There are usually multiple fang marks Numbness and weakness begin in the region of the bite within 10 to 15 min and are followed by ataxia ptosis pupillary dilatation and loss of reaction to light and accommodation, palatal and pharyngeal palsies slurring of speech salivation and occasionally nausea and vomiting The patient becomes comatose respirations falter there are convulsions and death occurs within 8 to 72 hr

Treatment An attempt should be made to determine with certainty that the patient has been bitten by a poisonous snake Absence of distinct fang punctures and failure of local pain edema numbness or weakness to appear within 20 min are strong evidence against a bite s having been inflicted by a venomous species

Treatment consists of immobilization application of a tourniquet incision and suction, antivenin refrigeration measures to combat infection and general support All patients should be transported to a hospital as quickly as possible

Local Measures A tourniquet should be placed a few centimeters above the bite (if anatomically feasible) and made tight enough to allow one finger

Treatment Atabrine as prescribed for taeniasis saginata (p 1138) is moderately effective

Prevention This is difficult since the problem is similar to that encountered in enterobiasis Only a single host is involved and the eggs are immediately infective Personal hygiene should be stressed The contamination of food by rats and mice should be prevented

Section 19 Disorders Due to Venoms

204 SNAKE BITE

Ivan L Bennett Jr

Fewer than one tenth of the nearly 2 500 known species of snakes are venomous These poisonous varieties belong to five families or subfamilies Elapidae (cobras kraits coral snakes) found in all parts of the world but Europe Viperidae (true vipers) found in all parts of the world but the Americas Hydrophidae (sea snakes) Crotalidae (pit vipers) found in Asia and the Americas and Colubridae represented by a few rear fanged species of Africa The poisonous varieties of the United States with the single exception of the coral snake of the Elapidae are pit vipers and include the rattlesnakes the water moccasin and the copperhead This discussion will center around these species but the therapeutic measures outlined are applicable to snake bites in all parts of the world

The number of individuals bitten by poisonous snakes in the United States is estimated at 2 000 to 3 000 per year deaths are not reported separately but are undoubtedly rare numbering fewer than 20 per year In many European countries deaths from snake bite have averaged only one every 3 to 5 years for the last half century In contrast the estimate of annual deaths from snake bite in Brazil is 2 000 (4 per 100 000 population) and 2 000 in Burma (15 4 per 100 000)

Etiology The coral snake is found in the Southern states from Florida to Arizona It is marked by alternating red and black bands separated by yellow rings Coral snakes are nocturnal and placid and rarely bite man The fangs are short and permanently erect the highly toxic venom is injected into multiple puncture wounds produced by a series of chewing movements

The pit vipers are so named because of a small pit between the eye and the nostril Large venom glands in the temporal region give the head a triangular appearance They are generally aggressive and likely to strike if disturbed The fangs are long and hinged folding posteriorly when the mouth is closed Pit vipers strike suddenly with a

can species These reptiles are not aggressive and virtually every instance of their attacking man has involved teasing or handling the animals in captivity The venom is elaborated in eight glands in the floor of the mouth and secreted directly into the oral cavity where it bathes the teeth which are grooved posteriorly The lizard clings tenaciously and is often dislodged only after considerable effort envenomation occurs by contamination of the wound The venom contains a potent neurotoxin which is undoubtedly responsible for its lethal effect in experimental animals Death in man has been reported as occurring within a few hours (in one case 30 min) after a bite The venom also produces local tissue injury excruciating pain massive edema and patchy erythema In recovered cases acute symptoms have lasted for 3 to 4 days and include nausea vomiting hematemesis blurred vision dyspnea dysphonia and profound weakness Intense hyperesthesia of the bitten extremity can persist for several weeks There is no antivenin available Treatment should consist of tourniquet incision suction measures to prevent or combat infection including tetanus and supportive measures Because Demerol has been shown to potentiate the venom s action in animals some other analgesic should be used to relieve pain

Spider Bite

The bite of many spiders can be locally irritating and several species are capable of causing severe sometimes fatal systemic poisoning By far the most numerous and important venomous spiders are the members of the genus *Latrodectus* which is widely distributed throughout the world In the United States and Canada *L mactans* the black widow or shoe button spider is the cause of nearly all clinically significant arachnidism In Florida another species *L bishopi* the red legged widow spider has been reported to produ e human poisoning resembling mild black widow bite The symptomatology and mortality from bites of large hairy spiders the tarantulas such as *Lycosa raptoria* and *Phoneutria fera* in Brazil and *Glyptocranium gasteracanthoides* in Peru differ in no important respects from those produced by *Lactrodectus* except that there is also severe necrosis and ulceration at the site of a tarantula bite

It is the female *L mactans* the black widow that bites man She is glossy black with a body 1 cm in diameter and a leg span of 5 cm There is a characteristic red hourglass" mark on the ventral abdomen (Fig 155) She spins her web in wood piles sheds basements or outdoor toilets is very aggressive and bites on slight provocation The venom is said to be about fifteen times as potent as that of the rattlesnake on a weight for weight basis It produces diffuse central and peripheral nervous excitement, autonomic activity muscle spasm hypertension and vasoconstriction

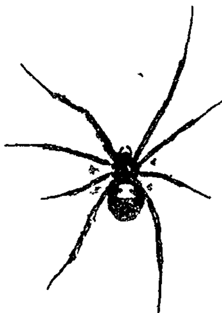

Fig 155 *Latrodectus mactans* female (black widow) Ventral surface showing the orange red "hourglass" spot (Approximately actual size) (*Stitt Strong "Diagnosis Prevention and Treatment of Tropical Diseases"* The Blakiston Division *McGraw Hill Book Company Inc New York*)

In the United States most spider bites occur between April and October and many patients are males bitten on the genitalia or buttocks while using a privy After a momentary sharp pain at the site there is cramping pain that begins locally within 15 to 60 min and gradually spreads It can involve all extremities and the trunk The abdomen is boardlike and the waves of pain become excruciating causing the patient to turn toss and cry out Respirations are often labored and grunting There are also nausea vomiting headache sweating salivation hyperactive reflexes twitching tremor paresthesias of hands and feet and occasionally systolic hypertension A mild polymorphonuclear leukocytosis is usual and many patients have fever up to 100 F After several hours the pains subside although mild recurrences for 2 or 3 days are common It may be a week before well being is restored Deaths have occurred mostly in children and the aged In an analysis of nearly 1 300 cases from the United States and Canada

to pass beneath it with difficulty The purpose is to impede lymph flow and it is not necessary to obstruct venous return the tourniquet should be *loosened* and *moved proximally* when local swelling causes it to tighten Using whatever antisepsis is available 1 cm cruciate incisions about 0 5 cm deep should be made through each fang mark and suction applied for at least 30 min A rubber bulb for this purpose is contained in first aid kits but a breast pump funnel attached to a vacuum line or heated jar can be used Mouth suction is permissible if no oral lesions are present Suction should be carried out for 15 min every hr then every 2 hr as long as fluid is obtainable As the swelling progresses successive rings of radiating linear shallow incisions at the advancing edge of the edema are useful such cuts will be expanded by the *progressive swelling* Once a patient has been hospitalized a pavex boot is a convenient means of applying suction to an extremity Extensive or deep slashes over the area are unnecessary Incision and suction are extremely important and should be carried out diligently in every poisonous snake bite Antivenin is not a substitute for them and should not be relied on alone

Immobilization of the affected part during transportation is important in controlling lymph flow splinting is useful in achieving this The application of ice packs to the affected area reduces inflammation and swelling slows drainage by lymphatics relieves pain and curtails local necrosis Care should be taken to avoid freezing the tissues

Antivenin Many of the components of venom are antigenic and effective antiserum can be prepared by inoculation of horses with graded doses In this country the only commercially available antivenin is *Antivenin Crotalidae Polyvalent (North and South American Antisnakebite Serum)* prepared by Wyeth Laboratories it is effective against all pit vipers Kits containing lyophilized antivenin (reconstituted with distilled water to 10 ml per ampul) syringe normal horse serum for prior sensitivity testing of the patient and detailed instructions are available The initial dose for a serious bite should be 5 ampuls intramuscularly and if antivenin is given within 2 hr after the bite 10 ml of this can be infiltrated locally Further antivenin can be given as indicated by progression of swelling or systemic symptoms

No antivenin for coral snakes is manufactured in the United States although antiserum is sometimes kept on hand in large zoos Soro Anti Elapidico is the commercial name of an effective serum against coral snake venom that is available from the Instituto Butantan Caixa Postal 65 Sao Paulo Brazil

The American Association for the Advancement of Science Symposium on Venoms listed among the references at the end of this chapter contains a complete listing of antivenin preparations and their sources throughout the world

Other Measures The maintenance of respiration by manual or mechanical aids is important in patients bitten by the elapine snakes It has been suggested that the cholinesterase of cobra and coral venom is responsible for much of the neurotoxicity and that neostigmine and atropine given as for myasthenia gravis might help This has not been tested clinically

Tetanus toxoid or antiserum should be given If pyogenic infection develops antibiotics should be used

Alcohol has no place in the treatment of snake bite Opiates are contraindicated Relief of pain with salicylates or Demerol sedation maintenance of fluid intake measures to combat shock and appropriate management of coma or convulsions are all important

Limited trials of ACTH and adrenal steroids have not shown any great usefulness of these hormones in lessening local necrosis or systemic intoxication

Prevention In snake infested regions long trousers high shoes boots or leggings and gloves should be worn Most important of all is to look where one steps or reaches A sharp knife or lancet tourniquet suction bulb and antiseptic suffice for an emergency kit and in inaccessible areas antivenin also should be carried

205 OTHER DISORDERS DUE TO VENOMS

Ivan L Bennett Jr

Gila Monster Bite

The Gila monsters include the large orange and black lizard (*Heloderma suspectum*) of the arid Southwest and *H horridum* a closely related Mexi

Cheyne Stokes breathing Pulmonary edema develops terminally The patient passes from an agitated state with hyperactive reflexes into coma convulsions follow Death usually occurs within 12 hr but sometimes as late as 2 days after the sting

Treatment This consists of immediately placing a tight ligature on the extremity just proximal to the sting followed by application of ice and as soon as possible immersion of the involved member above the ligature in ice water The ligature must be removed in 5 to 10 min but the limb is kept refrigerated for at least 2 hr After this time if treatment has been applied promptly it is said that no serious effects are experienced following the sting of *C sculpturatus* or *C gertschi* If the sting is on the head trunk or genitalia of course the ligature cannot be used but the area may be chilled with an ice pack

Other authors recommend tourniquet incision and suction as in the treatment of snake bite However the amount of venom is minute it produces no local necrotizing effect and is absorbed so rapidly that unless these procedures are carried out very promptly they are of doubtful value

Supportive therapy is directed at combating shock and dehydration Barbiturates in large doses are useful in reducing restlessness

Prevention This depends upon alertness in avoiding contact with scorpions in infested areas Clothing and shoes should be well shaken before being put on in the morning Towels and bedclothes should be inspected A house infested with scorpions can in time be rid of them by closing all obvious ways of ingress picking up debris in the environment such as piles of brush logs stones introducing a mixture of fuel oil or kerosene containing a small amount of creosote between the earth and the house foundation and spraying with a mixture of 2 per cent chlordane 10 per cent DDT and 0 2 per cent pyrethrins in an oil spray base The spray is applied in a band 3 ft wide to the outer walls to the undersurface of the house also to screens and crevices around windows and plumbing and under the eaves Inside the house the attic woodwork plumbing cupboard and closet interiors are similarly coated with the residual spray which under protected conditions has proved effective for as long as 6 months

Tick Paralysis

Tick paralysis is a reversible disorder of the nervous system which sometimes develops in the host while a tick is engorging It may occur in man or animals The disease has been reported from many countries It has long been recognized in the northwestern United States and western Canada where the wood tick *Dermacentor andersoni* Stiles is responsible More recently the dog tick *D variabilis* Say has been identified in a number of cases occurring in the Eastern states *Amblyomma americanum* the lone star tick and *A maculatum* the Gulf Coast tick have also been incriminated

While engorging the tick apparently injects a neurotoxin which acts upon the spinal cord and bulbar nuclei causing incoordination weakness and paralysis The toxin is rapidly destroyed or excreted for when the tick is removed the nerve cells soon regain normal function

Tick paralysis has been produced in experimental animals only with gravid female ticks suggesting that the toxin might be elaborated by the ova However injection of extracts prepared from tick eggs has failed to reproduce the clinical picture in convincing fashion

The tick must feed for several days before symptoms develop Female ticks commonly remain attached for 7 to 9 days or longer Paralysis is seen in experimental animals after 5 to 7 days of engorgement Male ticks feed for a shorter period a fact which may explain why they are less likely to cause paralysis

Experimental confirmation of the theory that the toxin is produced in tick salivary glands is also lacking It has been found that not all gravid female ticks of incriminated species cause paralysis The nature site of production and mode of action of the toxin have not been established

Most human cases occur in children generally in young girls The tick is usually attached to the scalp and hidden by the hair but may be found on any part of the body especially the ear axilla groin vulva or popliteal region Both white and Negro races are susceptible

The patient may be irritable for 24 hr before motor involvement appears Mild diarrhea may occur There is weakness and poor control of the legs The tendon reflexes in the legs are diminished or absent and the Romberg sign is positive Temporary improvement may occur and if the tick is removed at this stage true paralysis may never develop Otherwise the symptoms recur within 24 hr with flaccid paralysis which extends in one or more days to involve the trunk arms neck tongue and pharynx Sensory changes are usually absent but there may be paresthesia and hyperesthesia in the affected extremities Nystagmus strabismus and facial paralysis are sometimes noted The respirations become shallow rapid and finally irregular The patient sinks into stupor cyanosis appears and death results from respiratory paralysis or from obstruction of the airway by aspirated material

There is little or no fever unless a secondary

the mortality varied from 2 4 to 6 0 per cent This is higher than is usually stated

Because the bite itself is not prominent patients are often thought to have some abdominal catastrophe such as perforated ulcer pancreatitis or volvulus Renal colic coronary occlusion tetanus strychnine poisoning tabetic crisis lead colic and porphyria are other conditions to be ruled out The abdomen is not tender to palpation in arachnidism and pains in the extremities are not typical of most of these other disorders

Treatment This consists of antiserum and measures to relieve pain The antiserum is produced in horses by Merck Sharp and Dohme and a single intramuscular injection of one ampul (2 5 ml) of reconstituted material is all that is needed in most cases relief is gradual Hot baths alleviate pain temporarily and intravenous calcium gluconate or magnesium sulfate will produce dramatic but usually transient cessation of cramps Opiates are usually incompletely effective Neostigmine epinephrine and ACTH have all been reported to give relief in isolated cases and are worth trying

Bee Sting

Bee venom is hemolytic and neurotoxic and has a histaminelike action Multiple stings in man cause pain and discomfort but only in enormous numbers (500 to 1 000) can they cause death Apiarists become immune to the venom and can sustain many stings without effect

The usual reaction to a single bee or wasp sting is sharp pain local wheal and erythema intense itching and in loose tissues such as the eyelid or genitalia considerable local edema This subsides in a few hours Only in the rare case when a bee is inhaled or swallowed and edema of the laryngopharynx or glottis develops is there danger A sting directly into a peripheral nerve may destroy its function for a time much as does an injection of alcohol There have for example been cases of Bell s palsy following sting into the trunk of the facial nerve

In hypersensitive individuals a single sting may produce serious anaphylaxis with urticaria nausea abdominal cramps asthma massive edema of the face and glottis dyspnea cyanosis hypotension coma and death Sensitization is usually a result of previous stings beekeepers sometimes develop allergic rhinitis followed by asthma when near bees or objects that have been in contact with bees These individuals are likely to have serious reactions to a sting

Treatment The usual sting is treated by local cool applications and antipruritic lotions or oral antihistaminics Epinephrine 0 3 to 0 5 ml of 1 1000 aqueous solution subcutaneously repeated every 20 to 30 min may be lifesaving in allergic patients This drug can be given as 1 100 solution in oil intramuscularly Oxygen antihistaminic drugs and other supportive measures should be used Desensitization by injections of extracts of whole bees has been reported but if this is not practical *contact with bees should be avoided*

Scorpion Sting

Scorpions are eight legged arthropods Adults are 2 to 20 cm in length Glands in the terminal segment produce venom which is injected into the victim by a stinger located on the tip of the tail Scorpions often enter dwellings During the day they retreat into crevices emerging at night they often get into shoes and clothing and even into bedding They do not deliberately attack man but accidental contact results in a sting

Of about 650 species roughly 40 occur in the United States distributed over three fourths of the nation They are most numerous in the South from Florida to California but the only two lethal species *Centruroides sculpturatus* and *C gertschi* are limited to Arizona and portions of neighboring states In general scorpions are not encountered in New England and the Great Lakes area

The venom is neurotoxic It acts locally upon sensory nerves and centrally upon the medulla and involuntary nervous system causing circulatory respiratory and widespread autonomic disturbances

Dangerous species found in the United States *C sculpturatus* and *C gertschi* reach a maximal length of about 7 cm Their sting may be fatal to young children or old people but seldom to a healthy adult In the years 1929 to 1948 inclusive 68 deaths from scorpion sting were reported from the state of Arizona

Most of the nonlethal species of scorpions in the United States cause only minor reactions like a bee sting Some in the Southwest however produce local edema and ecchymosis with burning pain In contrast many species whose venom has potentially dangerous systemic effects including the Arizona *Centruroides* evoke little or no visible reaction at the site of the sting There is an immediate burning sensation followed by local paresthesia (pins and needles) hyperesthesia or numbness These spread to involve the whole extremity and within an hour or two malaise restlessness lacrimation rhinorrhea salivation perspiration nausea and vomiting appear The emeses may contain blood Transient hypertension glycosuria and premature ventricular contractions have been recorded In fatal cases dyspnea may occur without cyanosis Tachycardia with muffled heart sounds and feeble pulse may be noted or there may be bradycardia and respiratory depression with irregular or

Etiology Sarcoidosis attacks persons of all ages but is most likely to be encountered between the ages of twenty and forty It is probably quite a common affection and though Scandinavia is the cradle of the disease cases have been reported from most countries in Europe from Africa South America Japan and in increasing numbers from the United States In North America the Negro appears to be particularly susceptible and in this race the disease is recognized at a much earlier age than in the white Both sexes are affected equally

The incidence of the disease does not suggest a hereditary basis but there are accounts of families with two or more members suffering from it The disease often affects farm laborers or those who live in country districts In a study of military personnel a significantly greater frequency was noted among those whose birthplace had been in the southeastern United States

The cause is unknown On histologic grounds *there is considerable resemblance between sarcoidosis* and the effects of known bacterial infections such as tuberculosis leprosy and brucellosis fungous invasions and the effects of particulate matter such as beryllium but no relationship to any of these has been demonstrated Many regard the disorder as infectious in origin It is noteworthy that patients with sarcoid are more often refractory to tuberculin than are normal persons of comparable age sex, and race

Morbid Anatomy The characteristic lesion is a granuloma consisting of large pale epithelioid cells collected in isolated nests or well defined nodules the so-called "hard tubercles Pale multinucleated giant cells containing peculiar basophilic inclusions may be present Necrosis or caseation does not occur and there is no inflammatory zone about the clusters of epithelioid cells The evolution of the lesion is very slow but fibrosis ultimately develops Calcification does not take place The characteristic granulomas may be found in many parts of the body including the skin lymph nodes lungs bone marrow spleen liver mucous membranes salivary and lacrimal glands eye tonsil myocardium nervous system kidney prostate breast and testis The manifestations of the disease depend on the location of the lesions and may be those resulting from involvement of the lungs (polycythemia cor pulmonale) heart (arrhythmia failure) liver (hyperglobulinemia) thyroid (myxedema) pituitary (diabetes insipidus) nervous system (especially pareses and paralyses) kidneys (renal insufficiency) or testes (eunuchoidism)

Symptoms The onset is insidious as a rule the progress sluggish and the dissemination of the lesions is wide There is slow healing but relapse is frequent The condition harms essentially not by intoxication but by mechanical injury Longcope aptly stated that in its irregular progression with regressions and exacerbations and in its long periods of hidden latency sarcoidosis can only be compared to syphilis and tuberculosis while in its distribution throughout the body it can be likened to Hodgkin s disease

In uveoparotid fever after a period of malaise lassitude and indefinite gastrointestinal symptoms intermittent pyrexia of moderate degree may occur The parotid glands enlarge and are firm but painless Often one gland is affected later than the other The mouth may become very dry Uveitis usually follows the parotid involvement Conjunctivitis keratitis neuroretinitis or other types of ocular involvement may occur Seventh nerve paralysis unilateral or bilateral may follow or there may be other evidences of cranial nerve involvement or signs of a peripheral neuritis in one of the extremities may appear

Skin eruptions have been observed in 15 to 60 per cent of cases They may consist of (1) small discrete slightly elevated nodules varying in size from a few millimeters to a centimeter in diameter yellowish or purplish in color waxy in appearance and sometimes pitted in the center or umbilicated These are found usually over the face about the eyelids and nares or over the ears and around the shoulders and the upper extremities (2) large more or less lobulated granulomata which are firm and dry and frequently have a purplish tint These occur most conspicuously on the nose or about the joints of the hands and feet and (3) large flat very finely granular or scaly plaques that usually cover large areas of the skin principally over the extremities or trunk Pustulation and ulceration do not occur in any of the lesions but atrophic scars may remain when the lesions ultimately subside

Firm nodules may appear at the interphalangeal joints of the hands producing sometimes a knotty appearance There may be tightness or stiffness of the fingers In about 17 per cent of cases roentgenograms reveal rarefaction and trabeculation of the medullary portions of the shafts of the phalanges and metacarpal bones or punched out areas may be present in the small bones of the hands and feet (*osteitis tuberculosa multiplex cystoides*)

In other cases general lymphadenopathy attracts attention first The cervical submaxillary epitrochlear axillary and inguinal nodes may be involved but preauricular postauricular submaxillary and submental involvement are particularly suggestive of sarcoidosis The individual nodes are usually moderate in size firm in consistency discrete and not tender At the same time it is common to find that there is enlargement of lymph nodes in the

thorax especially in the hilar region where they may be massive (potato nodes) and in the peri bronchial and peritracheal area

Of all the internal organs the lungs are the most susceptible to involvement by sarcoidosis The lesions may be (1) miliary with tiny densities appearing throughout the whole lung field (2) linear extending fanwise from the hilum (3) nodular (4) diffuse and confluent or (5) combinations of these *The pulmonary disease may be asymptomatic* or pulmonary functional abnormalities may occur as reduced lung volume with mild hyperventilation and inconstant decrease in maximum breathing capacity or disturbances in alveolar capillary gas exchange (syndrome of alveolar capillary block) or the pattern may be that of chronic pulmonary emphysema

The cardiovascular system may sustain damage indirectly from the pulmonary disease or there may be direct invasion of the heart muscle Dyspnea and cyanosis are characteristic features of such cases

In the abdomen the lymph nodes the liver and the spleen are the most susceptible sites of the disease Although the intestinal tract is rarely affected the stomach may be involved and massive hemorrhage may occur Hepatic enlargement is the usual manifestation of disease in the liver but liver biopsy reveals focal granulomas in many cases There may be impaired Bromsulphalein excretion and other evidences of hepatic dysfunction Hyperbilirubinemia and frank jaundice are rare

Slight to moderate splenic enlargement has been observed in at least 25 per cent of the cases This may be accompanied by anemia leukopenia thrombocytopenia purpura signs of portal hypertension or no symptoms or signs whatever

In addition to fever at the onset of the disease when this is acute and when in particular it takes the form of uveoparotid fever fever of considerable *degree may be present with exacerbations of the* disease and in the late stages when extensive pulmonary lesions are present

Renal insufficiency renal calculi and nephrocalcinosis in addition to hypercalcemia are manifestations of sarcoidosis which may cause considerable confusion in diagnosis and may ultimately lead to death Granulomatous lesions are sometimes associated with the renal failure *but the latter may* occur even in their absence and is then accompanied by hypercalcemia and nephrocalcinosis and even hypercalcuria and renal calculi The cause of the hypercalcemia is obscure It is not necessarily related to widespread bone destruction *Increased* gastrointestinal absorption of calcium has been demonstrated in several cases and excessive endogenous production of vitamin D like substances has been postulated as the cause In some cases hypersensitivity to vitamin D seems to have been an aggravating factor

Laboratory Findings Anemia is unusual The leukocytes may be normal in number or there may be slight leukopenia Eosinophilia (6 to 35 per cent) and monocytosis have been noted in a number of cases The total plasma proteins are usually increased as a result of an increase in the gamma *globulin The serum calcium is often above normal* the phosphatase sometimes Pleocytosis and increased protein in the spinal fluid may be associated with the uveoparotid syndrome

Diagnosis The characteristic features of the skin lesions which suggest this disease are their occur*rence in groups bilaterally their persistence and* slow extension and their lack of tendency to ulcerate The finding or history of parotid swelling and uveal tract involvement perhaps with facial nerve palsy the invasion of the lacrimal and salivary glands the lymph node involvement and the lesions in the small bones of the hands and feet offer evidence strongly suggestive of sarcoidosis Slit lamp examination may disclose minute bodies typical of sarcoid in the iris or cornea

It is not rare however for these typical features to be lacking yet the finding sometimes accidental of enlarged hilar nodes or shadows in the lungs the existence of slight fever or a little weight loss vague abdominal pain or splenic or hepatic enlargement the discovery of lymphadenopathy or the presence of unexplained hemolytic anemia leukopenia or thrombocytopenic purpura demands intensive study and a search for the cause

Hodgkin s disease and tuberculosis in particular must be ruled out In sarcoidosis the constitutional reaction considering the degree of involvement is singularly inconspicuous as compared with that expected in Hodgkin s disease or tuberculosis and the Mantoux reaction and sputum are negative Silicosis *may be suggested by the pulmonary lesions* syphilis by the bone lesions and leprosy by the skin changes Periosteal changes are found in syphilis not in sarcoidosis The benign course and lack of constitutional symptoms rule out leprosy

Establishment of the diagnosis depends on biopsy of affected structures whenever possible Even small lymph nodes may show characteristic *changes When there is a pulmonary lesion* scalenus fat pad biopsy may reveal epithelioid cell granulomas Liver aspiration biopsy is also very useful and splenic and bone marrow biopsies are sometimes employed

The Nickerson Kveim cutaneous reaction has been found to be helpful in diagnosis and the incidence of false positive reactions is claimed to be low The test consists of the intradermal injec

tion of a heat sterilized suspension of human sarcoid tissue and histologic examination of the site of injection after 4 to 6 weeks As the disease process regresses the test result may become negative but positive responses have been observed in a few patients whose illness had begun even a decade earlier

Prognosis Spontaneous recovery may be anticipated in the majority of cases but the condition is apt to run a long course during which relapses with involvement of different organs and tissues alternate with quiescent or latent periods Death may result from the accumulation of sarcoids in the mediastinum lungs heart or central nervous system The uveoparotid syndrome usually disappears but some thickening of the parotid may persist and scars synechias and even blindness may follow eye involvement Renal failure may result from nephrocalcinosis Tuberculosis has been demonstrated in approximately 30 per cent of cases coming to autopsy

Treatment A variety of remedies have been tried including tuberculin arsenic gold ultraviolet rays roentgen rays radium and nitrogen mustard but their efficacy is difficult to assess Of greatest promise is the use of ACTH or cortisone With these agents a striking regression of signs and symptoms of active disease has been observed in many cases However the pattern of events after cessation of treatment has varied from prolonged remission to prompt relapse Where the disease has produced extensive fibrotic change little if any improvement has been observed

207 INFECTIOUS MONONUCLEOSIS

M M Wintrobe

Definition This is a disorder of unknown etiology usually benign and probably of infectious origin which is characterized by irregular fever sore throat lymphadenopathy and enlargement of the spleen as well as by an absolute lymphocytosis made up of cells of a peculiar type High concentrations of antibodies against sheep erythrocytes are usually demonstrable in the blood serum

History Since the designation "infectious mononucleosis" was first proposed by Sprunt and Evans in 1920 an ever increasing number of cases has been observed and reported especially since 1935 This is due at least in part to better recognition of the disease Prior to 1920 a few sporadic cases had been observed The relationship of epidemics in children described under the title of "glandular fever to infectious mononucleosis is uncertain

Etiology and Pathogenesis This is a disease of young people including children which has now been observed practically throughout the world In the United States infectious mononucleosis has been less frequent in Negroes than in white persons It is a relatively common condition in interns medical students and nurses but many cases among other persons undoubtedly pass unnoticed The mild or nonspecific character of many of the symptoms may be responsible or the fact that appropriate blood examinations have not been made With increasing frequency sporadic cases have been observed wherever young people live together as in boarding schools colleges and military groups

The etiology is unknown although it is generally believed that the disease is infectious in nature It is likely that individual susceptibility is low and that the causative agent is extremely labile No clear instances of successful experimental transmission to human subjects have been reported and in the main experiments both in man and in animals have yielded little knowledge as to the nature of the causative agent

Clinical Picture The clinical picture differs to some extent in accordance with the stage of the disease In the *prodromal period* which may be 3 to 6 days in duration the symptoms may be vague and nonspecific such as chilly sensations and slight fever malaise sore throat swollen

Table 98 SYMPTOMS AND SIGNS OF INFECTIOUS MONONUCLEOSIS EXCLUDING FEVER AND HEADACHE

Prodromata or early symptoms	*Per cent*	*1st and 2d week symptoms (excluding malaise)*	*Per cent*	*Late and/or convalescent signs and symptoms*
Malaise	51	Swollen cervical glands	77	Glands may remain enlarged for weeks—a small percent age
Sore throat	49	General glandular enlargement	70	Severe cases may leave the pa tients feeling below par for months
Swollen cervical glands	21	Throat		
Chills	20	Red	57	
Cough	12	Sore	50	
Eyes sore or pain back of eyes	10	Spleen enlarged	43	
Neck sore and stiff	9	Stomatitis and/or Vincent s angina	36	
Abdominal pain	7	Rash	15	
Pain in shoulder	4	Eye signs *	15	
		Liver enlarged	13	
		Jaundice	5	
		Cough	3	

* *These include swollen eyelids 5% conjunctivitis 5% pain in or back of eye 9%* photophobia *4%*
SOURCE Gardner and Paul Yale J Biol and Med 19 846 1947

cervical glands stiff neck and occasionally cough The temperature curve is irregular rising each evening to a higher level In the *midstage* the clin ical picture is more characteristic although the manifestations of this disorder are protean In this second week of the illness cervical glandular en largement is a very common sign (77 per cent of cases) and often the adenopathy is generalized The glands are single or in clumps but they are usually discrete and only slightly tender except where they drain a secondarily infected area The throat is often sore and in more than half the cases a brilliant red color can be observed in the pharynx over the arches soft palate and uvula At the same time there may be a translucent edema involving the soft palate and the uvula Such edema may be present even when there is no pain in the throat In other cases the throat presents the typical picture of follicular tonsillitis or that of Vincent s angina or of diphtheria Stomatitis may be present

A diffuse or patchy often morbilliform" rash usually limited to the trunk eye signs (conjunc tivitis pain in or back of the eyes photophobia) and jaundice may be encountered in various cases The liver may be found enlarged even in the ab- sence of jaundice and liver function tests indicate that hepatic involvement without symptoms is com mon The spleen is palpable in more than half the cases

This midstage lasts from 4 to 20 days and is followed by a *period of convalescence* which some times is slow and may be associated with marked prostration Recrudescences are very common Re lapse has occurred in about 6 per cent of cases Recovery is the rule but death has been observed in a few instances from such complications as rupture of the spleen respiratory paralysis in asso- ciation with nervous system involvement pneu monia edema of the glottis and hemorrhage from a deep tonsillar ulceration

Classification of infectious mononucleosis under the headings (1) glandular form (2) anginose type and (3) febrile type emphasizes the three most common forms of the disease but fails to make clear that this is a disorder of very diverse mani festations ranging from cases with no fever or con stitutional symptoms to those with severe prostrat ing complaints of great variety Headache may be so severe as to suggest meningitis Epistaxis pur pura hematuria rectal bleeding marked tachy cardia with cyanosis electrocardiographic evidence of cardiac involvement convulsions stupor coma stiff neck and various pareses and paralyses in volving cranial nerves or lower motor neurons are among other symptoms and signs which may de velop Involvement of mesenteric nodes may be as sociated with signs which mimic acute appendi citis

Blood Picture The leukocyte count is usually increased but in the first week especially there may be leukopenia due to granulocytopenia The leuko- cytosis is usually moderate (10 000 to 15 000 per cubic millimeter) but it may sometimes be very marked It is due to an increase in lymphocytes and these in the main are of a peculiar type their nucleus may be oval kidney shaped or slightly lobulated and the cytoplasm is often somewhat basophilic and may be vacuolated or foamy in ap pearance The nuclear chromatin is usually coarse and irregular and nucleoli are rarely seen These

cells make up 60 per cent or more of all the leukocytes

The characteristic changes in the leukocytes may appear as early as the second day of illness or as late as the twelfth day They attain a peak by the seventh to tenth day and persist usually for 1 to 2 months

Anemia is extremely rare but several instances of hemolytic anemia complicating infectious mononucleosis have been reported Thrombocytopenia is rare but in several cases the clinical picture resembled that of idiopathic thrombocytopenic purpura The bone marrow reveals a slight myeloid hyperplasia and immaturity there may be an increase in lymphocytes

The serum characteristically contains agglutinins against sheep red cells in high titer (heterophil antibodies Paul Bunnell test see Chap 109) This has been observed in different series in 60 to 100 per cent of cases The Paul Bunnell test is actually nonspecific Anti sheep agglutinins are present in titers up to 1 28 in most normal persons and occasionally even in a titer of 1 56 In various infections a titer of 1 112 and occasionally of 1 224 may be seen Persons receiving injections of horse serum and horse immune serum may develop titers as high as any seen in infectious mononucleosis For these reasons it is generally considered that in the presence of clinical and hematologic findings suggestive of infectious mononucleosis a titer of 1 224 or higher can be interpreted as confirming the diagnosis When there is doubt a differential test is required This is based on the observation that heterophil antibodies in normal serum in horse serum sensitization and in a variety of infections can be absorbed completely by guinea pig kidney On the other hand anti sheep agglutinins in infectious mononucleosis are never completely removed by treating the serum with guinea pig kidney although they are as a rule completely removed by beef red cells The differential test is carried out by absorbing a portion of the patient s serum with guinea pig kidney and an other portion with beef red cells After this the absorbed specimens are tested for sheep red cell agglutination

In infectious mononucleosis highest heterophil antibody titers are found usually during the second and third weeks of illness and as a rule positive reactions last 4 to 8 weeks The titer bears no relation to the severity of the disease or the degree of lymphocytosis The serologic test for syphilis may become transiently positive

Renal function is rarely impaired but albumin and red cells may be found in the *urine* The *cerebrospinal fluid* pressure may be moderately elevated and pleocytosis due to lymphocytes may be found

Diagnosis While glandular enlargement, sore throat fever the characteristic cells in the blood and an increased titer of heterophil antibodies are a combination of findings which makes recognition of this disease easy in many instances the protean manifestations of infectious mononucleosis may produce a clinical picture which taxes the acumen of the physician Acute appendicitis German measles follicular tonsillitis infectious hepatitis and influenza are a few of the diseases which may be simulated Acute leukemia is another But anemia the presence of very immature leukocytes and of nucleated red cells in the blood and thrombocytopenia as well as the characteristic bone marrow picture should make differentiation not difficult

As already indicated the clinical picture and the blood findings may be so characteristic that a diagnosis of infectious mononucleosis can be made at times with reasonable assurance in the absence of a positive heterophil antibody reaction A rising titer as the disease progresses is of significance even if the increase is only within the "normal" range In the absence of the characteristic blood picture the diagnosis of infectious mononucleosis is unjustified unless well-defined changes in heterophil antibodies are observed

The clinical picture may be like that of serum sickness a condition in which lymphocytes quite similar to those seen in infectious mononucleosis may be found and as indicated above a positive heterophil antibody test may be obtained The differential test is required to distinguish between the antibody reactions in infectious mononucleosis and the rise in titer produced by horse serum Lymphocytosis relative or absolute may be encountered regularly or occasionally in a number of the diseases with which infectious mononucleosis may be confused on clinical grounds Marked leukocytosis (40 000 or even higher) chiefly due to the presence of small lymphocytes of normal appearance characterizes a benign disorder *acute infectious lymphocytosis* which has been observed chiefly in children and is accompanied by only mild constitutional manifestations and no lymphadenopathy splenomegaly or positive heterophil agglutination reactions

Treatment It is treated symptomatically Controlled studies indicate that neither penicillin nor Aureomycin has any significant influence on the disease The irregular fever persists in most cases for 1 to 3 weeks and subjective symptoms disappear as a rule in 2 to 4 weeks *Relapses* are not uncommon and may be late but recurrences are very rare A positive heterophil antibody reaction may persist for as long as 5 or 6 months rarely longer Anamnestic reactions of heterophil antibodies in significant titers have not been described

208 REITER S SYNDROME

Max Michael Jr

Definition The eponym *Reiter s syndrome* designates a symptom complex comprising the triad of urethritis arthritis and conjunctivitis At times a diarrhea occurs and a variety of other visceral lesions may be present

Etiology and Epidemiology The etiology is unknown but the weight of evidence has incriminated either directly or indirectly members of the pleuropneumonia like group of organisms and the dysentery bacilli The earlier findings of a spirochete in the blood of a patient with the syndrome has not been corroborated Pleuropneumonia like organisms have been isolated from the urethra of a few patients with Reiter s syndrome and in rare instances these bacteria have been recovered from synovial fluid Since these organisms are difficult to detect it is possible that they may play an important etiologic role that has been overlooked for technical reasons Clinical observations have also suggested that bacillary dysentery is responsible for the development of the syndrome During the years 1943-46 344 cases of Reiter s syndrome were observed on the Karelian Isthmus where bacillary dysentery was endemic Whereas the incidence of Reiter s syndrome was 0 2 per cent in patients with dysentery dysentery preceded the onset of the syndrome in 96 4 per cent of the cases In the United States however it has been unusual to observe this relationship Reiter s syndrome usually affects young adult males and has only rarely been recorded in females and Negroes Whether sexual exposure constitutes the mode of infection remains a disputed point

Pathology A limited number of microscopic examinations of synovial tissue have been carried out These have demonstrated villous formation hyperemia and infiltrates of lymphocytes plasma cells and a few polymorphonuclear leukocytes The cellular infiltrates do not assume the nodular pattern observed in rheumatoid arthritis and pannus formation has not been observed

Clinical Features Urethritis conjunctivitis and polyarthritis usually follow each other in that order from 2 to 40 days or longer being required for the complete syndrome to manifest itself The *urethritis* varies from a slight serous discharge to a profuse purulent one It is as a rule more scanty than is that of gonorrhea The urethritis is of short duration in most instances and ceases before the onset of arthritis In those cases in which it persists for several months symptoms wax and wane Occasionally there is gross hematuria

Conjunctivitis usually bilateral varies from mild injection of the bulbar conjunctivas to an intense purulent inflammation Its duration is variable but is shorter than that of the arthritis It usually heals leaving no residua Keratitis iridocyclitis and corneal ulceration are occasionally noted *Arthritis* is most often polyarticular and involves principally weight bearing joints—in particular ankles and knees The small joints are only occasionally involved Joint pain is frequently of sudden onset several joints being affected within 2 or 3 days Heat redness and swelling both articular and periarticular are noted The splinting resulting from intensive muscle spasm can lead to contractures and deformities unless appropriate preventive measures are undertaken Arthralgia without objective findings is rare Arthritis persists from one month to over a year It always remains after the other features of the syndrome have subsided Involvement of tendons tendon sheaths and bursae may be noted

Other Manifestations Reiter s syndrome shows cutaneous lesions resembling keratodermia blennorrhagica ulcerations of the penis ulcerative lesions of the oral cavity cystitis proteinuria pleuritis pericarditis and myocarditis Mucocutaneous lesions seen most frequently in the genitourinary tract consist of small vesicles surrounded by an

erythematous papule The vesicle soon ruptures leaving a purulent crust which may become keratotic Splitting of the layers of the finger and toe nails as well as thick horny layers of the nails may be seen Diarrhea which is usually mild has been reported to precede many cases of Reiter syndrome by several weeks The occurrence of diarrhea as mentioned above has been particularly striking in the various series reported from military hospitals and in Finnish studies

The course of Reiter's syndrome is exceedingly variable Some patients are afebrile during the entire disease others may develop fevers as high as 104 F during the early stage of the disease The usual case shows low grade fever ranging from 100 to 101 F for about 2 weeks Recurrences which may occur from weeks to years after the initial episode are characteristic of the syndrome The recurrence may assume the pattern of the original attack or may consist of any combination of the triad It is probable that permanent joint destructive changes do not take place however contractures and muscle atrophy are not uncommon

Diagnosis By definition the diagnosis of Reiter's syndrome should be limited to those cases presenting the classic triad There has been a tendency to accept some cases in which certain features of the syndrome are lacking The chief diagnostic problem lies in its differentiation from gonococcal arthritis in which urethritis conjunctivitis and arthritis may occur Careful culture studies and the use of the gonococcal complement fixation test will usually clear up the dilemma (p 877) Rheumatoid arthritis may be confused with Reiter's syndrome particularly before the complete triad has developed Skin lesions and urethritis are rare in rheumatoid arthritis Moreover the arthritis of Reiter's syndrome is usually asymmetrical does not involve the interphalangeal joints as a rule and is only rarely accompanied by destruction of cartilage The differential sheep cell agglutination may be helpful (p 1720) Stevens-Johnson (p 1770) and Behcet's (p 1710) syndromes should cause no difficulty in differentiation as arthritis is rare in these entities and when present is mild

Treatment Salicylates are of value for the relief of pain The physical measures of rest heat massage muscle setting exercises and splints such as described for patients with rheumatoid arthritis should be undertaken (p 1721) Various authors have reported good results with either streptomycin or the broad spectrum antibiotics Possibly such results represent only the natural course of the disease with spontaneous remission but a trial of these agents for 10 days is warranted Adrenal corticoids and ACTH have been effective in ameliorating the acute inflammatory disease of eyes and joints and in permitting earlier and more active physiotherapy but the disease often flares up when hormones are discontinued

209 MIDLINE GRANULOMA

Lawrence E Shulman

Definition This peculiar condition, also known as *lethal midline granuloma* or *granuloma gangraenescens* is characterized by progressive destruction of the soft tissues and bony structures of the face terminating almost invariably in death after several months or a few years of illness It occurs in young adults and the middle aged and seems to be more common in males The first case was described by McBride in 1897 More than 100 cases have been reported mostly in the otolaryngologic literature

Etiology and Pathology Not only is the etiology of midline granuloma unknown but it is uncertain in which category of disease it belongs There is disagreement as to whether it is primarily (1) infectious (2) vascular or allergic or (3) neoplastic Only a few complete and detailed autopsy studies have been reported In half of them lesions have been found in parts of the body other than the face notably in skin lungs and mesenteric lymph nodes

Histologically the lesions of midline granuloma vary from case to case and also from one area to another in the individual case The most common finding in the facial lesions is nonspecific chronic inflammation In the face and elsewhere there are focal areas of necrosis and necrotic small blood vessels often containing granular thrombi suggesting that the process is primarily vascular The vascular lesions however differ from those of polyarteritis nodosa in that the characteristic inflammatory reaction is absent The lesions in some areas contain large numbers of cells of varying sizes with large pale multilobulated nuclei simulating Hodgkin's disease and mycosis fungoides In other areas hyperchromatic nuclei and numerous mitotic figures resemble those seen in undifferentiated tumors

Clinical Features Midline granuloma begins with a prodromal period of months to years of nasal obstruction and discharge at first mucoid and later purulent During this time the patient is usually thought to have allergic rhinitis or sinusitis Pro

209 MIDLINE GRANULOMA

Lawrence E Shulman

Definition This peculiar condition also known as *lethal midline granuloma* or *granuloma gangraenescens* is characterized by progressive destruction of the soft tissues and bony structures of the face terminating almost invariably in death after several months or a few years of illness It occurs in young adults and the middle aged and seems to be more common in males The first case was described by McBride in 1897 More than 100 cases have been reported mostly in the otolaryngologic literature

Etiology and Pathology Not only is the etiology of midline granuloma unknown but it is uncertain in which category of disease it belongs There is disagreement as to whether it is primarily (1) infectious (2) vascular or allergic or (3) neoplastic Only a few complete and detailed autopsy studies have been reported In half of them lesions have been found in parts of the body other than the face notably in skin lungs and mesenteric lymph nodes

Histologically the lesions of midline granuloma vary from case to case and also from one area to another in the individual case The most common finding in the facial lesions is nonspecific chronic inflammation In the face and elsewhere there are focal areas of necrosis and necrotic small blood vessels often containing granular thrombi suggesting that the process is primarily vascular The vascular lesions however differ from those of polyarteritis nodosa in that the characteristic inflammatory reaction is absent The lesions in some areas contain large numbers of cells of varying sizes with large pale multilobulated nuclei simulating Hodgkin s disease and mycosis fungoides In other areas hyperchromatic nuclei and numerous mitotic figures resemble those seen in undifferentiated tumors

Clinical Features Midline granuloma begins with a prodromal period of months to years of nasal obstruction and discharge at first mucoid and later purulent During this time the patient is usually thought to have allergic rhinitis or sinusitis Pro-

gressive inflammation and ulceration follow The first ulcerations are found in the nasal septum the mucosa or skin of the alae nasi or the center of the palate The lesions invade underlying cartilage and bone giving rise to septal or palatal perforations The condition spreads by local extension to involve the rest of the nose paranasal sinuses eyes mouth pharynx and larynx The bones of the midface are destroyed by erosion Gradually various important functions such as sight speech or ventilation are impaired or lost The end result is disappearance of most or all of the midface with the formation of a large cavity bounded above by the frontal bone and superior aspect of the orbits and below by the mandible which is never affected

During periods of activity and especially preterminally the patient becomes febrile Usually the fever does not respond to appropriate chemotherapy for secondary bacterial infection Moreover even in the presence of obvious pyogenic infection the patient often fails to develop leukocytosis and during the later stages may become chronically leukopenic Another curious feature is the absence of cervical lymphadenopathy during periods of active inflammation or infection A few patients showed raised indurated areas on the skin of the legs and abdomen resembling those of erythema nodosum *clinically and histologically There is no anemia and* the bone marrow is normal There are no serum protein abnormalities Microbiologic investigations have failed to detect a consistent specific pathogen

The course of the disease varies greatly some cases lasting for more than a decade with long periods of quiescence and other cases are fulminant ending fatally after a few months Death usually results from meningitis pneumonitis inanition or hemorrhage

Diagnosis During the early phases of midline granuloma it is important to rule out several specific nasal and facial conditions many of which are treatable These include leprosy syphilis yaws (gangosa) tuberculosis (lupus vulgaris) glanders leishmaniasis blastomycosis and coccidioidomycosis chromate poisoning lupus erythematosus also lymphomas mycosis fungoides and malignant tumors Midline granuloma is differentiated from Wegener s granulomatosis (p 1707) by the absence of generalized polyarteritis nodosa and glomerulonephritis Noma (p 881) is readily distinguished by its being largely restricted to children involving the cheeks and mouth but not the nose

Treatment No effective therapy for midline granuloma has yet been found The basic disease progresses despite administration of antibiotics or adrenocortical steroids A few early reports of benefit following radiotherapy have not been substantiated by further experience and nitrogen mustards have failed Radical surgical excision is no more effective than conservative debridement Various prostheses designed to maintain the integrity of the normal facial passages are helpful both functionally and cosmetically

Diseases Associated with Reactions to Stress and to Antigenic Substances

---

Section 1 Diseases Associated with Reactions to Stress and to Antigenic Substances

210 ALLERGIC DISEASES

Leighton E. Cluff

Definition Allergy or hypersensitivity in man designates the adverse reactions produced by exposure to a foreign substance (antigen) following an initial or sensitizing contact

Portier and Richet in 1902 coined the term *anaphylaxis* for the severe systemic reaction of dogs to reinoculation of foreign protein Four years later Roseman and Anderson showed conclusively that anaphylaxis is elicited only by the specific antigen to which an animal is sensitized The several local and systemic effects elicited by reexposure to antigen were referred to as *allergy* by Von Pirquet (1907) Jenner in 1801 observed acceleration of the local reaction to cowpox in immunized individuals and in 1890 Koch described sensitivity to tuberculin in patients with tuberculosis The relationship of pollen to hay fever and asthma was demonstrated by Blackley in 1865 and in 1903 Dunbar added animal dander and dusts to the list of antigens that commonly produce these disorders

Depending upon the character of the foreign substance that acts as antigen and the route of exposure to it allergy can appear in different forms In the *immediate* type of hypersensitivity the untoward reaction affects smooth muscle and blood vessels with resulting anaphylactic shock urticaria asthma hay fever or serum sickness (p 1697) Serum antibody to the antigen is usually demonstrable in this form of allergy and the hypersensitivity reaction often occurs after exposure via the respiratory tract Hypersensitivity of the *delayed* type is typified by the tuberculin reaction There is no association with serum antibody and exposure to antigen can result in damage to cells and tissues of many types This form of allergy is usually the result of bacterial infection or dermal exposure to antigenic substances

Asthma and hay fever are frequently familial and intracutaneous inoculation of the offending antigen often elicits an immediate wheal and erythema Allergy accompanied by these two features is commonly referred to as *atopic*

Etiology and Pathogenesis Contact with antigen is a prerequisite for development of allergy and hypersensitivity reactions are elicited only by reexposure to the antigen or some closely related substance The mechanisms involved in the interaction of antigen and antibody which leads to injurious effects however are poorly understood

The antigens in pollen dust and dander which are common causes of atopic allergy (manifested clinically as asthma) are probably proteins Specific antibodies associated with atopic allergy have features which distinguish them from antibodies of other types and are frequently referred to as *reagins* Reagins are not detectable by the usual in vitro immunologic procedures they are more resistant to heat than many other antibodies and they are firmly fixed at a local site of inoculation The presence of a reagin in serum correlates with the wheal and erythema elicited by intracutaneous injection of an antigen but bears no regular relationship to the presence or the severity of clinically significant allergic disease

Histamine is liberated by reactions of the immediate type and probably plays a role in producing some of the clinical manifestations of hypersensitivity Plasma proteolytic enzyme activity increases during certain hypersensitivity reactions but there is little evidence that it is responsible for the fundamental injurious effects The smooth muscle contraction characteristic of immediate hypersensitivity has led to the implication of acetylcholine in allergic reactions Changes in blood potassium adenosine serotonin heparin and many other substances have been described in allergic reactions but none of the biochemical abnormalities yet found has led to a satisfactory understanding of the mechanisms of hypersensitivity

Hypersensitivity itself is not inherited but the existence of a genetic predisposition to development of atopic allergy seems firmly established About 50 per cent of patients with hay fever or asthma will have a family history of allergic disease as opposed to only 15 per cent of the remaining population

Hay Fever

Hay fever is an allergic disease of man characterized by sneezing rhinorrhea itching of the eyes and lacrimation It is usually seasonal since sensitivity to air borne antigens particularly pollens is by far the most common cause Seasonal hay fever begins at an early age and is more frequent in

individuals from susceptible families Examination shows pale and edematous mucosa in the nose with secretion of large amounts of clear mucus

In *nonseasonal* hay fever there may be no family history of allergic disease There is often associated infection of the upper respiratory tract such as sinusitis Under this circumstance polyp formation in the nose is common

Eosinophils are abundant in nasal secretions and blood eosinophilia is common during atopic hay fever With coexistent respiratory infection however the secretions may predominantly contain neutrophils

Bronchial Asthma

Bronchial asthma is an allergic disease characterized by wheezing expiratory dyspnea and cough occurring spasmodically particularly after exposure to air borne antigens The respiratory manifestations are attributable to contraction of the bronchial and bronchiolar musculature edema of mucous membranes and accumulation of bronchial secretions In severe attacks hypoxia leads to cyanosis coma and rarely death Emphysema accompanies each paroxysm of acute asthma at first it is reversible but if the asthma occurs repeatedly it becomes intractable or permanent Paroxysms frequently begin at night Hyperexpansion of the thorax occurs and the diaphragm is low and relatively fixed Expiratory wheezes and rhonchi are heard *throughout the chest* The asthmatic attack may last for hours or days (status asthmaticus) With termination of the episode either spontaneously or after treatment the cough may become productive of large quantities of mucoid sputum containing small bronchial casts (Laennec s "perles and Curschmann s spirals) Anxiety is prominent during the asthmatic paroxysm Hay fever and urticaria sometimes precede development of asthma or occur simultaneously

Atopic asthma usually appears in young persons it is often seasonal and air borne antigens are almost always responsible Nonatopic asthma characteristically begins in older persons and is usually associated with chronic infection of the respiratory tract Air borne antigens do not seem to be the cause of this type and the disease has been termed "intrinsic asthma Intrinsic asthma is common in patients with chronic lung diseases of other types (see p 1387) Bronchial asthma is occasionally a principal manifestation of polyarteritis nodosa (p 1698)

Bronchial secretions in atopic asthma may contain eosinophils and blood eosinophilia is detected particularly when there are associated allergic skin reactions Radiologic examination of the chest during uncomplicated paroxysms usually shows depressed diaphragm and increased radiolucency of the lung The vital capacity is markedly reduced during an attack of asthma

Diagnosis Allergic reactions in the respiratory tract are identified entirely by their clinical characteristics

A history of allergic disease in the family—seasonal or recurrent attacks of nasal and bronchial symptoms or other allergic manifestations such as urticaria—is helpful in recognition of hay fever and bronchial asthma When hay fever and asthma occur during particular seasons or under certain environmental circumstances detection of the offending antigen is facilitated

The nasal mucous membrane in hay fever is pale and edematous in contrast to the reddened membrane observed in upper respiratory infection Pruritus about the eyes and nose is commoner in hay fever than in infection The presence of nasal polyps suggests coexistent infection and hay fever

Localized wheezing in the lungs is not a manifestation of bronchial asthma but is indicative of endobronchial disease such as foreign body aspiration neoplasm or stenosis In uncomplicated bronchial asthma examination of the lungs is usually normal between attacks Furthermore the wheezing and rhonchi occur almost exclusively in expiration whereas in bronchiectasis acute pulmonary *edema or pneumonia there are often inspiratory* rales as well "Cardiac asthma is occasionally indistinguishable from bronchial asthma The presence of inspiratory moist rales blood tinged sputum and cardiomegaly in cardiac asthma however is indicative of heart failure as the cause Poisoning with cholinergic drugs or insecticides may elicit manifestations of acute asthma which can be specifically relieved with atropine (p 778)

Skin Tests Intracutaneous inoculation of antigens is useful primarily for determining the reactivity of the patient to substances with which there has been environmental contact These tests are far less useful in specifying the antigens responsible for allergic disease Interpretation of skin reactions is dependent upon (1) the relationship of the allergic state to dermal reactivity (2) selection of the specific antigen for testing and (3) correlation of multiple hypersensitivities and the patient s disease Wheal and erythema reactions to a variety of antigens serve to designate a person as atopic or as having the propensity for developing an allergic illness upon exposure to the antigens Correlation of the skin test reaction with a historical analysis of allergic symptoms can facilitate determination of the agents responsible for symptoms Twenty five per cent of persons without allergic symptoms may have positive tests to common antigens the incidence is much higher in individuals with allergic disease In performing skin tests small doses of antigen should be used ini

tially Testing during an acute phase of hay fever or asthma is hazardous and should be avoided Treatment with adrenal cortical steroids will not interfere with the usual immediate" wheal and erythema reaction When it seems inadvisable to skin test a patient passive transfer of serum into the skin of a normal subject followed after a few hours by challenge at the same site with antigen may elicit wheal and erythema (Prausnitz Kustner reaction)

Therapy *Specific Treatment* Elimination of the offending antigen from the patients environment is the most successful means of preventing and treating allergic disease This is not always easy even when the antigen is known If it is determined that dander from dogs or cats is responsible these animals should be avoided A feather pillow may be replaced by one of foam rubber Air conditioning may alleviate symptoms produced by pollens The patient may be advised to move to a different location during periods when allergic symptoms arise Mechanical obstruction of the nares or tracheobronchial tree which may exaggerate the manifestations of hay fever or asthma should be corrected Complicating infection of the sinuses should be treated appropriately

Desensitization or *hyposensitization* of the patient is dependent upon recognition of the specific antigens which are the cause of an allergic disease Repeated inoculation of small amounts of antigen into sensitized persons or experimental animals is capable of suppressing reactivity to antigenic challenge The precise mechanisms involved are not well understood but under some circumstances this procedure results in production of a serum antibody (blocking) capable of inhibiting the reaction of antigen with reagins Subcutaneous inoculation of increasing amounts of antigen at intervals of a few days in dosage which does not elicit systemic or significant local discomfort may alleviate allergic symptoms Antigen can be given once or twice a week doubling each dose

If reaction occurs the dosage is kept the same or reduced after which increases can be given again An arbitrarily selected dosage level is maintained when satisfactory improvement appears Treatment by desensitization may be perennial seasonal or pre easonal Continued therapy throughout the year is probably preferable to discontinuous treatment In some instances the beneficial effects of desensitization may persist after the inoculations are discontinued but more often the allergic symptoms recur

Bacterial vaccines have been employed in desensitization of patients with nonatopic allergy Autogenous as well as standard vaccines are used The efficacy of this type of treatment however has not been fully established

Nonspecific Treatment HAY FEVER Hay fever is often alleviated by administration of antihistamines such as Benadryl or Pyribenzamine given in dosage of 50 mg three or four times each day As a rule however these agents lose their effectiveness after continued use Instillation into the nose of drugs such as Neo synephrine (¼ per cent) will shrink the edematous nasal mucosa but may if used repeatedly exaggerate and perpetuate the rhinitis Hydrocortisone and antihistamine nose drops also may provide temporary relief of the manifestations of hay fever Antibiotics should *not* be applied locally to the nares because they may induce sensitization Amphetamine inhalers can relieve an occluded nasal passage but continued use will cause persistence of nasal congestion *Systemic adrenal cortical steroids* frequently are effective in both atopic and nonatopic hay fever relieving symptoms and causing nasal polyps to disappear but long continued use carries the risk of side effects of steroid therapy (p 596) For temporary relief of acute symptoms however hydrocortisone in dosage of 200 mg per day can be very useful Prednisone may also be used but in about one fifth the dose of hydrocortisone (p 582)

In the usual case of hay fever nonspecific treatment with antihistamines should be used first If this is ineffective other therapy may be instituted particularly if the illness is disabling or severe

ASTHMA Treatment of acute asthma is most effective when begun soon after onset of the paroxysm Prompt relief can usually be achieved by subcutaneous injection of *epinephrine* 0 2 to 1 0 ml of a 1 1 000 solution repeated as needed but no oftener than every 30 min It is advisable to administer a sedative such as phenobarbital 60 to 90 mg with epinephrine to allay agitation and to relieve the anxiety accompanying an attack of asthma Epinephrine may become ineffective after repeated use It may be used in oil 1 0 ml of a 1 100 solution and injected intramuscularly for prolonged effect and may be vaporized as a 1 100 aqueous solution for inhalation Nebulized epinephrine analogues can be administered by the patient but if used repeatedly irritate the respiratory mucosa *Aminophylline* is an active bronchodilator which is beneficial in the person refractory to the action of epinephrine It may be used occasionally in preference to or in addition to epinephrine It may be given intravenously rectally or orally in decreasing order of effectiveness The dosage is 0 25 to 0 5 Gm When given intravenously the drug must be given slowly Rectal administration as a suppository or in water or oil is effective If the patient is cyanotic oxygen may be given but should be used intermittently particularly if chronic emphysema is present (p 1397) Ether administered rectally or as a general anesthetic may oc

casionally be successful in halting a severe attack of asthma *Adrenal cortical steroids* may be given in severe or intractable paroxysms in the same dosage as described for hay fever but are not always effective If an asthmatic episode is unresponsive to the use of epinephrine and aminophylline or recurs promptly it may be advisable to give a continuous intravenous infusion of 1 liter 5 per cent glucose containing 0 25 to 0 5 Gm aminophylline over 1 to 2 hr Morphine should never be given to the patient with acute asthma but *Demerol* 50 to 100 mg is useful as a sedative and antispasmodic Hydration should be maintained to prevent inspissation of bronchial mucus If inspissation of bronchial secretion develops bronchoscopy can be valuable Intractable asthma is commonly complicated by pulmonary infection and appropriate treatment may be beneficial Antibiotic therapy however must not be indiscriminate

Prophylactic management of the asthmatic patient involves the use of drugs with which the patient can abort paroxysms and institution of measures directed to improve general health Oral *ephedrine* (25 to 50 mg) and phenobarbital (30 to 60 mg) are commonly used to abort an asthmatic attack This drug combination is less effective in management of a fully developed asthmatic paroxysm *Aminophylline* (0 25 to 0 5 Gm) may be added to the combination of ephedrine and phenobarbital During a period of time when the patient is most likely to develop asthma ephedrine phenobarbital and aminophylline (APE) may be given three or four times each day When the patient is awakened at night by an attack of asthma aminophylline suppositories at bedtime are frequently effective in preventing the episodes Administration of *meprobamate* and other tranquilizing drugs has had some vogue in management of asthma possibly with a measure of success Similarly continued small doses of barbiturates have been used to allay the chronic anxiety occasionally displayed by some patients Psychotherapy has had little applicability

Smoking is undesirable in asthmatics as are obesity excessive exertion fatigue and dietary indiscretion

Atopic or seasonal asthma is most amenable to desensitization in contrast to nonatopic asthma Nonatopic asthma occasionally necessitates continuous administration of adrenal cortical steroids in order to suppress disabling symptoms Continuous administration of antibiotics to patients with nonatopic or intrinsic asthma is usually ineffective and unwise and will not prevent respiratory infection

Prognosis Hay fever is a benign disease principally uncomfortable and annoying to the afflicted person Bronchial asthma is also usually a benign disease and rarely causes death The only important prognostic implication of asthma is its causal relationship to obstructive emphysema which may produce pulmonary insufficiency cor pulmonale and cardiac failure The effective management of asthma however significantly lessens this possibility

Allergic Dermatitis

There are many dermatologic manifestations of allergic reactions including urticaria angioedema contact dermatitis erythematous rashes and eczematous eruptions The specific erythemas are discussed in the section beginning on page 1709

The hypersensitivity reactions responsible for allergic dermatitis may be of the immediate or the delayed type Contact dermatitis occurring after exposure of the skin to a sensitizing substance is accounted for by delayed hypersensitivity Urticaria angioedema and probably most erythematous eruptions are attributed to immediate hypersensitivity and usually develop after inhalation ingestion or parenteral inoculation of the antigen Allergic dermatitis due to delayed hypersensitivity is usually identified by means of a *patch* test with a resulting eczematous eruption at the site of application of antigen The immediate hypersensitivity responsible for allergic dermatitis can occasionally be determined by development of wheal and *erythema at the site of intradermal inoculation* of antigen

Contact dermatitis is probably the commonest type of allergic skin disease Many drugs chemicals plants and foods may induce such reactions The lesion produced varies in its clinical features but usually appears only in areas exposed to the offending substances As a rule the involved skin is eczematous and reddened There may or may not be pruritus Chronic involvement and scarification by scratching may cause lichenification of the skin

Diffuse allergic *eczematous dermatitis* occurs most often in young persons and is commonly a hypersensitivity reaction to foods or other ingested substances The principal lesions appear symmetrically in the antecubital popliteal neck or face regions Pruritus is usually severe and lichenification or chronic irritation of the skin may result from scratching *Neurodermatitis in adults* has similar distribution and clinical characteristics but is often attributed to stressful life situations and emotional disturbance

Identification and elimination of the offending antigen are the only satisfactory means of treatment Local or systemic administration of adrenal cortical steroids will usually suppress the dermatitis but recurrence is the rule when this treatment is discontinued if the antigen has not been eliminated

Other forms of treatment such as the application of soothing lotions are usually not very beneficial and furthermore may result in development of hypersensitivity reaction to the therapeutic agent

211 ALLERGIC REACTIONS TO DRUGS

Leighton E Cluff

The increase in allergy to drugs parallels the growing use of pharmaceutic agents in the management of disease With the continual introduction of new drugs this problem can be expected to become even more serious

Definition Classification of a drug reaction is not always easy but undesired responses to therapeutic agents have certain specific features which facilitate their characterization Nearly all drugs can elicit pharmacologic effects other than those for which they are administered and when these appear they are referred to as *side effects* or *toxic effects* Some patients exhibit unusual susceptibility to the pharmacologic actions of a drug and are said to have an *idiosyncrasy* In addition reactions not explained by the pharmacologic properties of a drug and therefore indicative of altered reactivity of the patient are termed *allergic* Side effects as a rule are intensified by increasing dosage or cumulative action and readministration is not associated with increased reactivity of the patient For example nausea hyperpnea and tinnitus in a person given large doses of aspirin are side effects and reduction in dosage will usually alleviate the situation The occasional patient who displays these symptoms after taking a small amount of aspirin has an idiosyncrasy to the drug However if ingestion of aspirin is followed by bronchial asthma or urticaria reactions not explainable by the drugs pharmacologic action the patient is allergic to it This type of reaction is likely to be associated with symptoms commonly ascribed to hypersensitivity (rash asthma pruritus arthritis fever leukopenia etc) frequently recurs promptly on readministration of the drug and is not closely dependent on dosage or cumulative action

The clinical importance of differentiating side effects idiosyncrasy and allergy relates of course to the hazard of readministration of a drug or its probable safety in lower dosage

Etiology Allergy is believed to result from the formation of specific antibody to a drug However most pharmacologic agents are incapable of stimulating antibody formation by themselves and it is thought that the actual antigen is a conjugate of the drug with serum or tissue proteins Under such circumstances the drug would act as a hapten nonantigenic by itself but conferring specific antigenicity to the protein and capable of combining with the antibody formed in response to the drug protein conjugate In support of this concept are the many demonstrations of binding of drugs by body proteins as well as experimental evidence that the ability of chemical compounds to elicit hypersensitivity can be correlated with their affinities for proteins

In the majority of instances the usual techniques for demonstrating antibody yield negative findings in drug allergy Precipitation hemagglutination or complement fixation tests with a patient s serum may be negative and direct intradermal or passive transfer tests of the Prausnitz Kustner type are often unrevealing Such results however are more indicative of the inadequacy of present methods of testing than an argument against an immunologic basis for hypersensitivity to drugs The lack of consistently effective testing methods is of course a great handicap to clinical investigations of drug reactions

Manifestations The commonest manifestations of allergy to drugs are no different from hypersensitivity reactions of other types and include rashes asthma and the symptoms of serum sickness (see Table 99) These are easily recognized clinically as allergic in origin Other features of drug allergy are sometimes less easily characterized however The tabulation see p 1164 of this chapter of common drugs and reactions which they may elicit includes some effects that may not be allergic at all A few examples of allergic drug reactions will illustrate the variations seen with different pharmacologic agents

Skin Morbilliform urticarial and maculopapular rashes are the most common skin reactions but many others are observed including vesicular bullous exfoliative eczematous and purpuric eruptions Pruritus is frequent Although *the type of* skin lesion usually will not aid in identifying the

causative drug there are certain skin reactions which are somewhat specific Erythema multiforme or nodosum is particularly seen in allergy to Dilantin bromides iodides trimethadione and sulfonamides Fixed drug eruptions are most frequently due to amidopyrine phenolphthalein or Atabrine Photosensitization during drug therapy *occurs characteristically with chlorpromazine* phenothiazine sulfonamides and tetracycline derivatives

Fever Fever may be an isolated manifestation of drug allergy and at least 35 pharmaceuticals in common use can produce a febrile reaction including most antibiotics and chemotherapeutic agents However the tetracycline derivatives are uncommon causes of drug fever and digitalis has rarely if ever been incriminated as the cause of a pyrogenic reaction Elevation of temperature can appear abruptly after initiation of treatment or develop in a stepwise fashion during or after the second week of drug administration Drug fever is often associated with chills and constitutional symptoms Discontinuance of therapy usually results in defervescence within a very few hours although several days may be required for return of temperature to normal

Blood Changes in the formed elements of the blood are rather common during drug allergy and may have no specificity Some drugs have been found to have limited or no effects on the blood while others produce specific abnormalities For example penicillin has never been incriminated as a cause of serious hematologic abnormalities In therapeutic doses acetanilid is probably not a cause of *anemia agranulocytosis thrombocytopenia* or *aplastic anemia* in high dosage however it may produce *leukocytosis methemoglobinemia* and *acute hemolysis* Methemoglobinemia also occurs with antipyrine nitrites sulfonamides primaquine and pamaquine but this reaction is probably not allergic in origin Barbiturates salicylates and para aminosalicylic acid rarely if ever produce agranulocytosis Eosinophilia can accompany allergic reactions of many types but occurs with such frequency as an isolated finding during therapy with streptomycin or nirvanol that it has no significance in these instances *Lymphocytosis* is common in patients receiving Dilantin and nirvanol but *polymorphonuclear leukocytosis may be found in individuals taking* Dilantin or atropine Recent studies of the erythrocyte abnormality responsible for the acute hemolytic anemia induced by primaquine in certain individuals indicates that what was thought to be drug allergy is actually a genetically determined idiosyncrasy (p 1184) *Jaundice* and *acquired hemolytic anemia* due to pharmaceutic agents are discussed elsewhere (p 1181)

Nervous System A variety of neurologic manifestations may appear during drug therapy but in the majority of instances there is little evidence to incriminate allergy as a cause The commonest reaction by far is delirium seen particularly with digitalis atropine thiocyanates and sedatives Other drugs which produce adverse effects upon the nervous system (ranging from paresthesias and peripheral neuritis to deafness) are streptomycin hydralazine chlorpromazine Diamox isoniazid polymyxin and neomycin

Others Nausea vomiting and diarrhea are exceedingly common drug reactions In addition abdominal pain in the absence of other symptoms may be produced by quinidine chlorpromazine and primaquine Albuminuria and cylindruria occur particularly with heavy metals bacitracin and polymyxin However Dilantin chloral hydrate sulfonamides trimethadione Phenurone colchicine and thiocyanate occasionally produce renal dysfunction probably by direct toxic action Hypersensitivity to sulfonamides has resulted in acute hemorrhagic nephritis

Histologic lesions indistinguishable from those of periarteritis nodosa have been found in the tissues of patients who have experienced allergic reactions to iodides Dilantin sulfonamides and penicillin (p 1698) Manifestations of systemic lupus erythematosus have appeared during therapy with gold or hydralazine (p 1700)

Anaphylaxis may follow the parenteral administration of a variety of drugs but the agent most seriously incriminated at present is penicillin Development of anaphylaxis has been reported after oral ingestion of the drug but this is exceedingly rare

The incidence of drug allergy is not high and is particularly related to the frequency with which a pharmacologic agent is used clinically For this reason probably these reactions are now often observed with antibiotics However the incidence of allergic reaction also varies with the agent and with some drugs may be as high as 10 per cent

Treatment and Prophylaxis Allergic reactions to drugs usually subside promptly when the agent is discontinued For reasons that are not understood however the reaction occasionally persists for prolonged periods in spite of withdrawal recurrent urticaria for many months after a penicillin reaction is a common example The management of serum sickness is described elsewhere (p 1697) In the event of persistent or severe manifestations of drug allergy the use of adrenocortical steroids is indicated Adrenal steroids antihistamines and adrenalin are usually ineffective in alleviating reactions due to idiosyncrasy or side effects of a drug Reactions of this type are best managed by adminis

tration of other drugs with appropriate pharmacologic actions i e sedatives for excitability stimulants for depression etc and by withdrawal of the offending drug

Although it is not possible to predict the occurrence of drug allergy in a patient the fact that hypersensitivity to drugs may be commoner in individuals with other allergic reactions makes it reasonable to inquire about this before initiation of treatment with any agent A specific history of hypersensitivity to a given drug contraindicates its readministration unless the clinical situation is serious In a number of instances where it has been judged necessary to prescribe a drug to which a patient is known to be allergic (e g penicillin for bacterial endocarditis) the concomitant administration of adrenal steroids has completely suppressed the manifestations of hypersensitivity

Although it is commonly said that sensitivity to a drug will subside if its administration is continued this is not a regular occurrence and should not be accepted as a basis for further therapy with the incriminated agent

PART EIGHT

Diseases of Organ Systems

Section 1 The Hematopoietic System

M M Wintrobe

The hematopoietic system includes the circulating blood the bone marrow the spleen and the lymph nodes supplemented by the reticuloendothelial cells scattered about the body The liver through the presence there of reticuloendothelial cells as well as by reason of other functions is also intimately concerned in blood formation and destruction Since the function of the red corpuscles is to hold in nondiffusible form the pigment hemoglobin essential for the transport of oxygen any alteration in the quantity of red corpuscles or in their hemoglobin content affects the function of all the organs of the body An important function of the leukocytes is to take part in the reaction to injury particularly in the defense against infection The blood platelets are concerned in maintaining the integrity of the vascular endothelium and in the clotting of blood The blood plasma which carries these three types of corpuscles is also the medium for the transport of many substances concerned in the metabolism of the organism

Since the blood and its constituents are so intimately related to the body as a whole much will be found concerning the blood in various chapters *in this book and particularly in those in Part Two* In regard to the red blood corpuscles attention should be called especially to Chap 12 (Hypoxia Cyanosis and Polycythemia) and to Chap 22 (Pallor and Anemia) In the latter the synthesis and the destruction of hemoglobin and the classification and management of anemia are considered as well as the pathogenesis symptomatology and methods of study of a patient with anemia The platelets the phenomenon of coagulation and the various ways in which bleeding is produced receive attention in Chap 23 (Bleeding)

In the present section disorders of the hematopoietic system will be considered It is evident that such disorders make themselves known in a variety of ways These may be such that discovering their cause may tax the acumen of even the most discerning physician In the main however they are characterized in part or whole by symptoms and signs such as pallor cyanosis jaundice bleeding or enlargement of the lymph nodes or spleen A thorough understanding of these manifestations of disease is a prerequisite to the correct differentiation as well as the effective treatment of the disorders of the hematopoietic system

The *approach* to the patient suspected of having a hematopoietic disorder is discussed therefore in Part Two under headings such as Bleeding Enlargement of Lymph Nodes and Spleen Anoxia Cyanosis and Polycythemia Although in the subsequent pages descriptions of the various recognized disorders of the hematopoietic system will be found and their treatment discussed it is urged that the reader confronted with a problem for example of anemia first study Chap 22 because he will find there a discussion of anemias in general and he will thereby make his way more readily through the pages that follow or for that matter through other sections in this textbook The same is true in principle if the problem is one of bleeding or cyanosis or splenomegaly

212 THE ANEMIAS

M M Wintrobe

POSTHEMORRHAGIC ANEMIA

Anemia resulting from blood loss may have developed suddenly because of the rapid loss of a large quantity of blood or it may have come about very gradually over a period of many months or even years Obviously there are also many possible variations between these two extremes The causes of posthemorrhagic anemia are numerous and the manifestations differ widely the latter depending in part on the nature of the underlying disorder and in part on the quantity and speed of the blood loss It is convenient to consider acute and chronic posthemorrhagic anemias separately because their *manifestations and in certain respects their treatment* differ so greatly It should be realized however that these two syndromes represent two extremes depending in the main on the same underlying defect and that in practice variations will be encountered which represent all stages between these extremes

Acute Posthemorrhagic Anemia

Etiology Trauma the rupture of a peptic ulcer or of an ectopic pregnancy and bleeding in connection with hemophilia or purpura hemorrhagica

are examples of the widely varied possible causes of acute blood loss They indicate that the blood loss may be external and recognizable at once or internal and consequently sometimes not readily discovered

Symptomatology The rapid loss of blood leads to reduction in blood volume and the clinical manifestations are mainly circulatory If the blood loss is great acute posthemorrhagic shock develops (see Chap 14) If the hemorrhage is visible to the patient whether the amount of blood lost is great or small symptoms may arise from the psychic effect of such bleeding Generally speaking symptoms are likely to appear sooner and are more pronounced in relation to the amount of blood lost when the bleeding is external than when it is not recognizable by the patient The manifestations of anemia in general have been discussed already (p 202) In addition the symptoms of the underlying disorder may be present as well

Blood Picture Polymorphonuclear leukocytosis with the appearance of immature forms (shift to the left) is the first discernible change An increase in platelets often takes place as well The anemia may not be apparent at once since at first plasma is lost as well as red corpuscles so that the ratio of cells to plasma remains the same As fluid is drawn from the tissues to restore the blood volume anemia becomes apparent This is normocytic at first Blood loss in an otherwise healthy organism however profoundly stimulates the bone marrow This becomes hyperplastic and immature corpuscles are liberated in larger numbers than usual Reticulocytosis ensues polychromatophilia is found and even nucleated red corpuscles find their way into the blood At this stage the anemia may be macrocytic since the immature cells are larger than the older forms Reticulocytes begin to appear within 48 hr following a brisk hemorrhage and may continue to increase for several more days A persistent reticulocytosis forming a plateaulike curve suggests that bleeding is continuing for cessation of hemorrhage is marked by quick restoration of physiologic balance with rapid regression of the signs of stimulated hematopoiesis If the iron stores of the body are good and the blood loss has not been extreme iron deficiency does not occur and hypochromia is slight or absent When the drain on iron is greater than can be readily replenished iron deficiency begins

When the acute hemorrhage is internal destruction of the blood and absorption of the products may lead to an increased excretion of urobilinogen in the urine and stools and rarely even slight bilirubinemia may be found Bowel hemorrhage is often associated with an increase in the blood urea nitrogen level

Diagnosis When acute hemorrhage is not evident such signs as pallor faintness restlessness sweating and palpitation should lead to a search for hemorrhage If the subject is recumbent much blood may be lost before these signs appear They can be brought out by tilting the patient to the erect position Late signs of acute blood loss are air hunger thirst and a falling blood pressure

Prognosis The amount and rapidity of the blood loss the acuteness of the physician in discovering it the availability of blood for transfusion and the accessibility of the site of bleeding are the important considerations

Treatment Stopping of the hemorrhage and restoration of the blood volume to normal preferably by transfusions of whole blood otherwise by administration of plasma or other fluids are the essentials Speed in restoration of blood volume is more important than whether plasma or whole blood is used If the blood loss has been great and the blood volume is profoundly reduced multiple portals should be used for administration of blood and even intraarterial administration may be advisable Fluids by mouth (unless the bleeding is from the upper portion of the alimentary tract) and by hypodermoclysis are valuable adjuncts as are rest and quiet induced by morphine if necessary Following the acute phase a good diet containing meat fruit and vegetables affords the proteins and vitamins needed for erythropoiesis Iron can be given in the form of ferrous sulfate (0 2 to 0 4 Gm t i d) but is not needed in previously normal individuals unless blood loss has been great

Chronic Posthemorrhagic Anemia

This refers to that state in which blood loss has produced a chronic anemia and a deficiency of substances necessary for blood formation has developed Although the factors essential for erythropoiesis are many the chief deficiency resulting from chronic blood loss is that of iron The manifestations of chronic posthemorrhagic anemia can therefore be discussed in the section which follows

IRON DEFICIENCY ANEMIA (Hypochromic Microcytic Anemia Idiopathic Chronic or Nutritional Hypochromic Anemia Chlorosis Chlorotic Anemia Chloranemia)

Etiology Iron is normally obtained by digestion of food and is absorbed chiefly in the upper portion of the gastrointestinal tract This is aided by the acid secretion of the stomach The absorbed iron is utilized for hemoglobin formation as well as for the production of myoglobin and other enzymes Normally a large reserve is stored in the liver spleen and other tissues The total iron store in man which is available for blood formation has been estimated to amount to 1 2 or 1 5 Gm Once absorbed iron is conserved tenaciously The amount

lost per day by the normal adult male has been estimated as approximately 1 mg

Any circumstance which leads to a greater demand on the iron stores of the body than can be supplied results in iron deficiency In logical order the possible factors leading to iron deficiency are (1) insufficient iron in the diet (2) impaired absorption (3) increased requirements and (4) loss of blood Of these the *chronic loss of blood* by hemorrhage is by far the most common factor in the development of iron deficiency Excessive menstruation and occult bleeding from the gastrointestinal tract (peptic ulcer esophageal varices hookworm infection etc) are the most common types of bleeding which may result in iron deficiency since the former is but an exaggeration of a physiologic process and may thus receive little attention while the latter may pass unnoticed for a long time

Impaired absorption of iron is rarely an important factor in the development of iron deficiency even though various influences favor or inhibit the availability and absorption of iron Thus a high level of calcium in the diet diminishes the formation of insoluble iron phosphates and favors absorption of iron but excess calcium inhibits iron assimilation Ascorbic acid favors iron assimilation probably by promoting the reduction of ferric iron in food to the ferrous form Although the gastric hydrochloric acid favors ionization and thus absorption many persons are encountered in whom achlorhydria has existed for years without iron deficiency developing Chronic diarrhea however is of more importance Certainly iron deficiency may be encountered in sprue

Deficiency of iron in the diet alone is rarely a cause of iron deficiency except in infants receiving a milk diet exclusively and occasionally in elderly people who although they have had no blood loss for many years have depleted their stores by consuming a diet very low in iron

In children and adolescents the iron needs for *growth* are very important and it is largely because of the demands made by the ever-expanding blood volume that infants receiving an unsupplemented diet of milk develop iron deficiency In older children and adolescents poverty or faulty habits may contribute to the mounting deficiency by causing consumption of a diet too low in iron to supply the needs In girls the menstrual loss of blood accentuates this deficiency Normal menstruation results in an average loss of 0 5 to 1 0 mg iron per day *Chlorosis* the green sickness" of the last century and before was probably no more than iron deficiency in adolescent girls in whom low dietary iron was insufficient to meet the needs In adult women the iron requirement during *pregnancy* and *lactation* are factors which may lead to the development of iron deficiency anemia Pregnancy results in a net deficit of iron of approximately 1 mg per day lactation about 0 5 mg per day Often these circumstances are superimposed on a state of gradually increasing iron depletion which may have had its beginning in adolescence The ultimate combined effect of chronic loss of blood increased demands and faulty diet may not become clearly manifest until thirty to forty five years of age the period in which the *chronic hypochromic anemia* of women is most often seen It is of interest that in such individuals certain *constitutional features* similar to those encountered in pernicious anemia may be observed such as early graying of the hair and achlorhydria

Since so little iron is excreted normally iron deficiency develops *in the adult male* only from loss of blood or from dietary deficiency or impaired absorption which has existed over a period of many years In the male ulcerative lesions in the gastrointestinal tract are by far the most likely causes of long continued undetected loss of blood

Symptomatology The symptoms are those common to all chronic anemias and may include a variety of vague gastrointestinal complaints such as anorexia capricious appetite or heartburn and more rarely sore tongue sore mouth and dysphagia (Plummer Vinson syndrome) or palpitation dyspnea and edema about the ankles or neuralgic pains vasomotor disturbances or numbness and tingling Menstrual disturbances are common—menorrhagia irregularity of flow or even phases of amenorrhea

A tired lifeless appearance pallor inelastic and often dry and wrinkled skin sometimes with a brownish hue dry and often scanty hair and blue scleras are found in cases of long standing In many some degree of papillary atrophy of the tongue slight cardiac enlargement functional systolic murmurs and a palpable spleen are discernible When the deficiency is severe the nails may be flattened longitudinally ridged or even concave (koilonychia) and may break easily The sore tongue dysphagia and changes in the hair nails and skin may occur in iron deficiency prior to the development of anemia

Blood Picture A good blood smear will reveal thin pale red corpuscles poorly filled with hemoglobin In some cases these may be mere rings Tiny microcytes target like cells elliptic cells and bizarre poikilocytes are also found as well as a certain proportion of normally filled corpuscles The anemia is hypochromic and microcytic Only in this type of anemia is a substantially reduced mean corpuscular hemoglobin concentration (MCHC) encountered (less than 30 per cent) This hypochromia is more significant than the microcytosis although the latter may be extreme (mean corpuscular volume 55 to 75 cuμ) The

red corpuscle count may be normal or nearly so or even greater than normal while the hemoglobin and volume of packed red corpuscles are greatly reduced The leukocyte count is normal or slightly reduced and a slight thrombocytopenia may exist

The *bone marrow* is hyperplastic and contains an excessive number of normoblasts

Diagnosis The symptoms are naturally varied since iron deficiency may result from a large variety of causes When iron depletion is only moderate in degree the changes in the blood may not be striking In more advanced cases adequate examination of the blood should make it clear that hypochromic microcytic anemia exists This type of anemia is most often due to lack of iron Experimentally a similar anemia is observed in copper and in pyridoxine deficiency but in man such deficiencies are exceedingly rare if they occur at all Metabolic disorders involving these substances have been described however Thus there is a syndrome in infants and young children in which low serum copper values and hypoproteinemia accompany a hypochromic microcytic anemia which responds to iron therapy Again an adult man has been described whose refractory hypochromic anemia responded to pyridoxine Also in two men hypochromic anemia together with hyperferremia has been described which failed to respond to all therapeutic measures other than the oral administration of a crude liquid extract of liver Again under the title of *hereditary sex linked (?) anemia* a form of hypochromic microcytic anemia accompanied by marked poikilocytosis and splenomegaly was described as affecting males though transmitted only by females This anemia failed to respond to any form of therapy and must be exceedingly rare as are the other examples of hypochromic microcytic anemia just mentioned The only form of anemia of this type which is not extremely rare and which may be mistaken for that due to iron deficiency is thalassemia (p 1192) Consequently the discovery of hypochromic microcytic anemia usually calls for a search for causes of iron deficiency and in particular requires a thorough search for sources of blood loss

Prognosis This is excellent in so far as the possibility of relieving the anemia is concerned The prognosis otherwise depends on the character of the contributory causes

Treatment Only in iron deficiency anemia is iron therapy of value Here the administration of *ferrous sulfate* or *ferrous gluconate* is followed by a reticulocyte response and subsequently rapid red corpuscle regeneration occurs Gastric irritation is less likely to occur if tablets of 0 2 to 0 3 Gm are taken on a full stomach To allow the patient to become accustomed to it at first a total of 0 4 to 0 6 Gm is given per day but this may be increased to 1 or 1 2 Gm In addition to iron therapy a good diet containing meat fruit and vegetables is to be recommended and any underlying or associated disorder should be corrected Transfusion of blood is rarely if ever needed even in the most anemic and free hydrochloric acid is not required even if achlorhydria is present Failure to respond to oral iron therapy necessitating intravenous administration has been described but is exceedingly rare

MACROCYTIC ANEMIAS

Elucidation of the pathogenesis of pernicious anemia even though still incomplete has made it clear that there are a number of closely related disorders which have in common a characteristic type of anemia megaloblastic hyperplasia of the bone marrow and the capacity to respond to liver therapy yeast pteroylglutamic acid vitamin B_{12} or related substances These conditions the *megaloblastic macrocytic anemias* must be differentiated from those instances of macrocytosis which represent increases in mean corpuscular volume from other causes usually from the presence in the circulation of a relatively large number of immature red corpuscles appearing in response to such hematopoietic stimulants as severe hemorrhage or acute blood destruction (Table 100) In this second type of macrocytic anemia the bone marrow is not megaloblastic and liver vitamin B_{12} or folic acid therapy has no value The clinical differentiation is usually easy

Pernicious Anemia (Addisonian Pernicious Anemia Addison s or Biermer s Anemia Primary Anemia)

Definition Pernicious anemia is a chronic disorder characterized by macrocytic anemia megaloblastic hyperplasia of the bone marrow gastric achlorhydria and often glossitis and changes in the nervous system This disorder appears to be the consequence of a permanent gastric secretory defect associated with atrophy which results in a deficiency in the body of a substance derived from food The deficiency can be corrected by supplying a substance present in certain liver extracts which appears to be identical with vitamin B_{12}

History Although the disorder was described at least as early as 1823 by Combe it was the picture given by Thomas Addison in 1855 and the comprehensive description by Biermer in 1872 which drew attention to this ultimately fatal (therefore "pernicious) anemia *The discovery of the value* of liver therapy by Minot and Murphy in 1926 and the elucidation of the role of the stomach in the pathogenesis of the disorder by Castle in 1929

Table 100 CLASSIFICATION OF MACROCYTIC ANEMIAS

I Megaloblastic macrocytic anemias

A Conditions responding to administration of purified liver extract vitamin B_{12} or pteroylglutamic acid (PGA)

Disorder	*Probable pathogenesis*
1 Pernicious anemia	Lack of gastric (intrinsic) factor
2 Sprue idiopathic steatorrhea	Impaired absorption
3 Resection of small intestine	Diversion of PGA and B_{12} from host
4 Nontropical nutritional macrocytic anemia	Dietary deficiency
5 Tropical macrocytic anemia	Dietary deficiency
6 Macrocytic anemia with *Diphyllobothrium* infestation	Assimilation of vitamin B_{12} by worm thus depriving host
B Conditions apparently responding only or most often to administration of PGA rather than vitamin B_{12}	
7 Megaloblastic anemia of infancy	PGA deficiency associated with dietary deficiency of ascorbic acid
8 Megaloblastic anemia of pregnancy	Dietary deficiency? Increased requirements for fetus? Presence of inhibitor or antagonist?
9 Refractory megaloblastic anemia	Impaired metabolism of PGA?
10 Achrestic anemia	Impaired metabolism of PGA?
II Nonmegaloblastic macrocytic anemias	
Some instance of macrocytosis due to	
1 Acute posthemorrhagic anemia	Presence in blood of many immature erythrocytes
2 Hemolytic anemia	Presence in blood of many immature erythrocytes
3 Aplastic anemia	Unknown
4 Hypothyroidism	Unknown
5 Liver disease	Unknown

Pernicious anemia is distinguished from the other conditions listed in that achlorhydria is always present and neurologic changes may occur

N B In practice the most common cause of macrocytic anemia is laboratory error and this is most often due to errors in red corpuscle counting

completely changed the prognosis of the condition and profoundly stimulated hematologic research in general

Etiology This disorder is very rare in persons under the age of thirty and is encountered much more frequently in light haired blue eyed individuals than in the darker races or in Orientals It is seen especially in natives of the British Isles the Scandinavian countries and other more northern regions as well as in their offspring in other parts of the world Nevertheless although less common pernicious anemia is seen in Negroes

A familial incidence is not unusual Those affected often have turned gray prematurely and they may have broad faces and large bony frames Males and females are affected about equally

That a gastric secretory defect is a fundamental factor in the pathogenesis of pernicious anemia was suspected almost as early as the disease was recognized It was shown later that absence of hydrochloric acid in the gastric secretion and a greatly reduced total gastric secretion (achylia) precede the development of the anemia by many years It has also been shown that such achylia is a defect which persists in spite of successful antianemic therapy Castle demonstrated that the significant abnormality in gastric secretion is not lack of hydrochloric acid but absence of an intrinsic factor which normally acts upon an extrinsic factor derived from food The material so produced was regarded as leading to the formation of a substance stored in the liver without which normal hematopoiesis cannot take place The gastric factor is thermolabile It seems to be contained in or adsorbed to the glandular mucoprotein of the stomach The thermostable food factor is present in meat eggs cereals and other natural sources of the vitamin B complex and is also present in liver Desiccated hog s stomach given orally has the same hematopoietic effect in pernicious anemia as liver and its effectiveness was assumed to be due to the interaction of the intrinsic and extrinsic factors in gastric tissue

The discovery of vitamin B_{1} (cyanocobalamin) a red pigment containing cobalt and the demonstration of its therapeutic effectiveness in pernicious anemia on parenteral administration in amounts as small as 1 μg has clarified some of the puzzling aspects of the pathogenesis of this disease Vitamin B_{1} is also active orally if given in very large

amounts (60 to 100 μg) but its hematopoietic effectiveness is greatly increased by normal human gastric juice Vitamin B_1 is apparently the extrinsic factor as well as the liver factor or anti pernicious anemia principle The role of the gastric or intrinsic factor is simply to promote the absorption of vitamin B_1 from the alimentary tract possibly through an action on the intestinal wall rather than on vitamin B_1 itself Because of the absence of intrinsic factor in cases of pernicious anemia the absorption of vitamin B_1 is impaired and the effects of deficiency ultimately develop

The vitamin pteroylglutamic acid (folic acid) has been shown to produce a hematopoietic response in pernicious anemia when given orally or parenterally It is neither Castle s intrinsic factor nor the extrinsic factor In nature it is found in conjugated form as the heptaglutamate (yeast) or as triglutamate An observation of great practical importance is that whereas the administration of liver extract or vitamin B_1 prevents the development or advancement of the neural manifestations of pernicious anemia these may appear in spite of folic acid therapy

It seems likely that vitamin B_1 and folic acid act as coenzymes at different stages in the biologic synthesis of nucleoproteins and that a deficiency of either or both results in a number of abnormalities of which megaloblastic bone marrow is the most readily recognized In explanation of the progress of the neural changes observed in some patients with pernicious anemia receiving folic acid therapy it has been suggested that folic acid influences only desoxyribonucleic acid (DNA) synthesis whereas vitamin B_1 is necessary for the production of ribonucleic acid (RNA) as well as DNA If the latter is required particularly by the bone marrow it is possible that the administration of folic acid while correcting hematologic manifestations tends to exhaust the limited supply of materials needed for RNA synthesis the latter being important for the nervous system

The red corpuscles of patients with untreated pernicious anemia appear to have a shortened survival time Thus the bilirubinemia and urobilinogenuria so characteristic of pernicious anemia would seem to be manifestations of a more rapid blood destruction which may be the consequence of imperfect construction of the red corpuscles resulting from a deficiency of building materials That this is not the sole explanation of the disturbance in pigment metabolism in pernicious anemia however is suggested by the observation that 40 per cent or more of labeled stool urobilin in pernicious anemia is not derived from circulating red corpuscles Some of the pigment apparently comes from heme or hematin which has not been used for hemoglobin synthesis

Pathology The significant findings are in the alimentary tract the bone marrow and the nervous system The tongue usually appears smooth and the papillae may be absent Atrophy of the mucous membrane may be striking in the tongue and in the stomach The changes in the stomach have been observed particularly in the fundic zone where the parietal and chief cells are usually absent

Appropriate staining reveals the liver as well as the spleen and kidneys to be abnormally laden with iron In the liver this is found in the periphery of the lobules and in the Kupffer cells There may also be fatty degeneration in the central cells of the lobules of the liver The heavy deposit of iron is the consequence of the fault in red corpuscle formation which leads to the development of anemia when active blood regeneration follows liver therapy the iron is used in blood formation

The *bone marrow* is red and is found to be crowded with cells Cells of the red series make up 30 to 50 per cent rather than about 20 per cent of the cells of the marrow The degree of hyperplasia and the degree of immaturity of the cells are roughly proportional to the severity of the anemia The nucleated red corpuscles (megaloblasts) differ from those found in other types of anemia in several respects They are exceptionally large and what is more significant the nuclear chromatin is fine and sievelike unlike the relatively coarse and lumpy material seen in normoblasts The cytoplasm of these cells may be polychromatophilic or orthochromatic and in a few is basophilic Many abnormal mitotic figures may be present At the same time extraordinarily large leukocytes may be found in the marrow in particular large metamyelocytes can be seen with bizarre shaped nuclei and peculiarly staining or vacuolated cytoplasm Megakaryocytes may be reduced in number and may be morphologically abnormal In spite of the evidence of cellular activity hematopoiesis is inefficient and anemia develops

In the nervous system degenerative changes may be found in the dorsal and lateral tracts of the cord in the dorsal root ganglions and in the peripheral nerves Myelin degeneration and loss of nerve fibers occur *More rarely changes are encountered in the* brain

Symptomatology The onset of the disease is generally insidious In many instances at least two of the diagnostic triad of symptoms are encountered namely weakness sore tongue and numbness and tingling in the extremities However other complaints may overshadow these and the presenting clinical picture may suggest some disorder of the digestive tract because of anorexia diarrhea and various other gastrointestinal symptoms it may simulate cardiac dysfunction of the anginal or the congestive failure type or one may be led to search

for some malignant neoplasm or an obscure infection In some instances the neural involvement is *so pronounced that a primary neurologic disease* is considered Even renal or genitourinary disease or a mental disorder may be simulated

The degree of soreness of the tongue varies *greatly and the involvement may be complete or* patchy The tongue may be beefy red when the symptoms are pronounced and is less red and smooth when they subside The gastrointestinal *symptoms are very variable However* one consistently found in relapse is anorexia Symptoms referable to the circulatory system include dyspnea palpitation sensations of extra beats weakness *vertigo tinnitus and precordial pain* Since pernicious anemia often appears for the first time in the older age groups it may be difficult to determine to what extent anemia or the degenerative changes of old age have contributed to the development of heart failure

Pallor a flabby rather than wasted appearance a slight or pronounced *yellowish color of the skin* together with faint icterus of the scleras a tongue which is often glazed in appearance and sometimes is red and sore a rapid pulse with slight cardiac *enlargement and often precordial hemic murmurs* in many a spleen which is just palpable and often a slightly enlarged liver are the chief findings outside the nervous system In the nervous system *loss of vibratory sense in the lower extremities (not* necessarily symmetric) incoordination of the lower extremities loss of finer coordination of the fingers signs suggestive of lateral as well as posterior spinal *cord involvement and evidence of peripheral nerve* degeneration are the most common findings and may be present in all degrees from slight or none to extensive involvement Positive Babinski response positive Romberg's sign disturbed position sense spasticity increased or diminished reflexes and sphincter disturbances may be encountered *Minor mental disturbances* (irritability memory disturbances mild depression) or more serious mental symptoms may develop

Laboratory Findings *Blood* The anemia is usually *more severe than the complaints and physical* examination would lead one to suspect In the blood smear macrocytes often oval in shape are characteristically seen (Fig 156) but there is actually a great range in the size of the cells and in addition many bizarre shaped corpuscles are found (poikilocytosis) Since the abnormally large cells *predominate the mean corpuscular volume* is found to be greater than normal and ranges between 100 and 160 μ (Fig 157) There is a corresponding increase in the hemoglobin content of the red corpuscles (mean corpuscular hemoglobin) so that the concentration of hemoglobin in the corpuscles (mean corpuscular hemoglobin concen

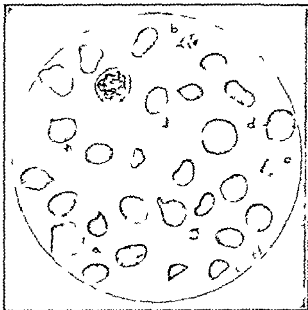

FIG 156 Drawing of a blood smear from a case of pernicious anemia in relapse From a preparation stained with Wright's and magnified ×960 Note the extreme variation in the size and shape of the red corpuscles the large polychromatophilic red corpuscle (*a*) the cells *containing nuclear remnants* and Howell Jolly bodies (*b c*) and a Cabot ring (*c*) the granular red corpuscle (*d*) and the multisegmented polymorphonuclear leukocyte (*Wintrobe Clinical Hematology" Philadelphia Lea & Febiger*)

tration) is normal The red corpuscles in pernicious anemia and in other macrocytic anemias are not "hyperchromic but being thicker as well as larger in diameter than normal corpuscles they appear to be supersaturated with hemoglobin as one looks *at them through a microscope Some degree of* diffuse polychromatophilia as well as basophilic stippling is found and occasional nucleated red corpuscles may be encountered The most striking changes described in classic cases are observed only when the anemia is very severe Since the anemia is macrocytic the red corpuscle count is *reduced more than proportionately as compared* with the hemoglobin or the volume of packed red corpuscles Reticulocytes are usually within normal limits in untreated patients or at most do not run higher than 3 or 4 per cent

The leukocyte count is usually lower than normal chiefly because of a granulocytopenia Thus there *is relative lymphocytosis* The polymorphonuclear neutrophilic leukocytes often show an unusual number of segments and may be exceptionally large An occasional myelocyte is present in many cases Sometimes *some degree of eosinophilia is* encountered The platelets are generally reduced in number sometimes to levels below 100 000 per cubic

amounts (60 to 100 μg) but its hematopoietic effectiveness is greatly increased by normal human gastric juice Vitamin B_{12} is apparently the extrinsic factor as well as the liver factor or anti pernicious anemia principle The role of the gastric or intrinsic factor is simply to promote the absorption of vitamin B_{12} from the alimentary tract possibly through an action on the intestinal wall rather than on vitamin B_{12} itself Because of the absence of intrinsic factor in cases of pernicious anemia the absorption of vitamin B_{12} is impaired and the effects of deficiency ultimately develop

The vitamin pteroylglutamic acid (folic acid) has been shown to produce a hematopoietic response in pernicious anemia when given orally or parenterally It is neither Castle's intrinsic factor nor the extrinsic factor In nature it is found in conjugated form as the heptaglutamate (yeast) or as triglutamate An observation of great practical importance is that whereas the administration of liver extract or vitamin B_{12} prevents the development or advancement of the neural manifestations of pernicious anemia these may appear in spite of folic acid therapy

for 7 to 10 days until a positive or negative result has been obtained

The discovery of vitamin B_1 and the fact that the cobalt contained therein can be labeled radioactively have provided a method whereby the absorption of this vitamin can be measured. This provides a means by which defective absorption of the vitamin from the gastrointestinal tract can be demonstrated even in the absence of anemia as in treated cases of pernicious anemia and to some extent megaloblastic macrocytic anemias other than pernicious anemia can be differentiated from that condition. Several different techniques are available but the most commonly used one the *Schilling test* depends on measurement of the excretion of the administered radioactive material in the urine. When radioactive vitamin B_1 is given by mouth to persons who can absorb it radioactivity will appear in the urine if the person is flooded with an intramuscular injection of nonradioactive vitamin B_1. Normal individuals have been found to excrete 7 to 22 per cent of the orally administered radioactivity in the urine in 24 hr with an average of 14 2 per cent. Patients with pernicious anemia have been observed to excrete only 0 to 2 3 per cent under these conditions. In them the simultaneous administration of intrinsic factor and radioactive vitamin results in increased excretion up to 3 1 to 30 per cent

Prognosis. With appropriate therapy it is now possible to restore the blood to normal and to promote a return of the general nutrition to normal. If changes are present in the nervous system their advance can at least be halted and in some cases improvement may take place. The danger in pernicious anemia arises from failure to continue therapy and from complications and intercurrent conditions. In a chronic ailment like pernicious anemia other diseases develop in the course of time. Among these carcinoma of the stomach is particularly noteworthy since the incidence of this disease in patients with pernicious anemia is more than three times as great as in other individuals. When changes in the nervous system exist particularly if they involve the urinary sphincter infection may occur. The existence of infection at the time of relapse may seriously interfere with the response to therapy

Treatment Treatment in so far as the blood changes are concerned is extremely simple. The administration of an adequate amount of liver extract or vitamin B_1 is followed by a reticulocyte response which reaches its maximum 5 to 7 or 8 days following initiation of therapy. This is succeeded as the reticulocyte count falls to normal by a rapid disappearance of anemia and by the production of cells of normal size and shape. The leukocyte and the platelet counts likewise return to normal bilirubinemia disappears and the increased quantities of urobilinogen in the urine and stools are reduced to the normal range. The gastric achlorhydria persists

Effective treatment may produce subjective improvement within 48 hr and evidence of a change is often noted by the patient before the reticulocytes increase. There is a gain in appetite and a sense of well being. Tongue symptoms if present disappear promptly. On the other hand neural symptoms do not change quickly. Although in the course of 2 months from the beginning of treatment the patient usually attains a normal blood the neurologic symptoms may still be present however those of milder intensity may have decreased or disappeared

The most efficient means of treatment is by the intramuscular injection of vitamin B_1. The effects of the administration of vitamin B_1 in pernicious anemia appear to be in every way similar to those produced by liver extract and like the latter are very much more pronounced when the vitamin is given parenterally than when it is taken orally (60 to 100 times). The minimal effective intramuscular dose of vitamin B_1 is 1 μg and good hematopoietic responses may be expected from doses of 10 μg daily. Larger amounts up to 80 μg or more daily produce greater effects the mean response being roughly proportional to the logarithm of the dose. As larger doses are given however a greater proportion is promptly excreted

For a patient in relapse between 1 000 and 5 000 μg vitamin B_1 is given since the substance is needed not only to produce a remission but to replenish the greatly depleted body stores. However this is best administered in divided doses in the course of the first 2 weeks or more of therapy otherwise much of the vitamin will be excreted before it can be used or stored as already indicated. An injection of 100 μg is a satisfactory amount to be given at one time. If possible reticulocytes should be counted daily in order that the effectiveness of therapy may be demonstrated early. An increased quantity of red cells as measured by the volume of packed red cells is not usually detectable before 10 days

Maintenance therapy may be calculated on the basis of approximately 2 μg vitamin B_1 for each day but this does not need to be given at intervals shorter than a month or two i e 60 μg is injected intramuscularly every 30 days or 120 μg every 60 days

Intravenous therapy is unnecessary. Oral therapy with liver extract or B_1 –intrinsic factor combinations is inconvenient since daily intake is necessary. Only where some idiosyncrasy on the part of the patient exists or where sensitivity to the parenteral administration of vitamin B_1 cannot be overcome otherwise is oral therapy justified. The substances available are dry or liquid liver extract powdered

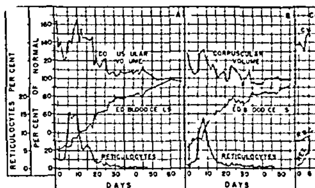

FIG 157 Variations in mean volume of red corpuscles compared with reticulocyte count in three cases of pernicious anemia The mean corpuscular volume (CV) and the red cell count (RBC) are represented as percentages of their respective average normal values By this method the red cell count and mean corpuscular volume of a hypothetic normal individual would fall on the line at 100 per cent Reticulocytes are recorded directly The abscissa records days following the commencement of liver therapy (Wintrobe *Relation of Variations in Mean Corpuscular Volume to Number of Reticulocytes in Pernicious Anemia J Clin Invest* 13 669 1934)

millimeter and bizarre forms including giant platelets may be found When there is thrombocytopenia the bleeding time may be prolonged the blood clot retracts poorly and purpura may develop

The resistance of the red corpuscles to hypotonic saline solutions is not significantly altered The icterus index usually ranges between 8 and 15 sometimes it is as high as 20 or 25 The average plasma bilirubin content is 1 mg per 100 ml but sometimes is higher and the van den Bergh reaction is "indirect"

Other Laboratory Findings With extremely rare exceptions there is in cases of pernicious anemia persistent failure to secrete hydrochloric acid in the stomach even following the injection of histamine Furthermore in the great majority of cases the enzymes are deficient as well and only a small amount of mucus rewards the gastric extraction

In addition to the bilirubinemia already mentioned the urobilinogen content of the urine and stools is increased Detailed examinations reveal many other evidences of metabolic disturbance involving especially protein and uric acid as well as fat metabolism

Diagnosis When the combination of the classic symptoms weakness sore tongue and numbness and tingling together with macrocytic anemia and achlorhydria is found there need be no difficulty in diagnosis Confusion may arise if the symptoms have led one to suspect some other condition and the blood examination has not been appropriate to demonstrate the existence of a macrocytic anemia Confusion may also arise when symptoms referable to the nervous system are prominent and anemia is only moderate or slight in degree For all practical purposes since achlorhydria is so characteristic a feature of pernicious anemia a diagnosis of pernicious anemia should never be made without demonstrating a failure to secrete hydrochloric acid following the injection of histamine The existence of a macrocytic anemia as indicated by calculation of red corpuscle size should furthermore be confirmed by examination of the blood smear In practically all cases such anemia is found to be associated with evidences of altered pigment metabolism such as some increase in plasma bilirubin and an increased output of urobilinogen in the urine and stools Where anemia is slight in degree the combination of achlorhydria slight macrocytosis as indicated by calculation of mean corpuscular volume and by the presence of macrocytes in the blood smear together with a slight degree of bilirubinemia makes the case highly likely

It must be kept in mind that the demonstration of macrocytic anemia is not in itself diagnostic of pernicious anemia for as already indicated macrocytic anemia may appear under a variety of circumstances When the macrocytic anemia is part of another disorder such as "aplastic" anemia "aleukemic" leukemia or some type of hemolytic anemia differentiation is important for vitamin B_1 or folic acid therapy is then valueless In aplastic anemia achlorhydria is only sometimes present glossitis is rare and signs of involvement of the nervous system such as loss of vibratory sense are unusual In aleukemic leukemia, sternal marrow examination should reveal a characteristic picture quite different from that of pernicious anemia and in hemolytic anemia the marrow is normoblastic not megaloblastic Even when the macrocytic anemia is accompanied by megaloblastic bone marrow differentiation is important since some forms unlike pernicious anemia are not permanent in character and do not require treatment for the remainder of the patient's life Certain rare megaloblastic macrocytic anemias furthermore do not respond to the administration of refined liver extract or to vitamin B_1 Some of these conditions are described briefly below

It is important that diagnosis be established accurately before treatment is initiated since as already indicated a diagnosis of pernicious anemia implies the need for therapy for the rest of the patient's life In doubtful cases a *therapeutic test* if properly performed can be very helpful It is important however that the test be made with vitamin B_1 alone and not with some agent containing iron or other substances in addition and that the reticulocyte response be observed daily

genesis of the macrocytic anemia seen in association with *intestinal strictures* and *anastomoses* has been attributed to impaired absorption but the fact that good hematopoietic responses have been observed when Aureomycin or Terramycin was given makes plausible the thesis that the anemia is caused by the colonization of the small intestine by abnormal bacteria which in some way divert folic acid or vitamin B_{12} from the host

The available evidence suggests that vitamin B_{12} and folic acid act as coenzymes at different stages in the biologic synthesis of nucleoproteins (p 1176) and that a deficiency of either or both results in a number of abnormalities of which megaloblastic bone marrow is the most readily recognized Under certain circumstances dietary deficiency of folic acid may develop and result in nutritional macrocytic anemia In other patients there may be defective absorption of folic acid (sprue idiopathic steatorrhea) but in some such patients the absorption of vitamin B_{12} may be impaired as well In still other cases alterations in the gastrointestinal tract may lead to consumption or destruction of one or both of these substances or an antimetabolite may be produced there (fish tapeworm anemia intestinal strictures and anastomoses) Only following total gastrectomy is absorption of vitamin B_{12} impaired in a manner corresponding to that encountered in pernicious anemia i e as the result of lack of intrinsic factor Various combinations of defects in dietary content absorption consumption destruction or antagonism may result in various degrees of deficiency of vitamin B_{12} or folic acid or both In addition it has been postulated that vitamin B_{12} in some manner influences the storage absorption and utilization of folic acid and that when vitamin B_{12} is lacking these functions are impaired

Quite unexplained are the more than a dozen instances of megaloblastic macrocytic anemia which have been observed in patients undergoing anticonvulsant therapy with either diphenylhydantoin sodium or Promidone Prohibition of the anticonvulsant particularly when associated with administration of folic acid resulted in complete relief of the anemia

Although macrocytic anemia is seen in some cases of hypothyroidism it is noteworthy that the bone marrow is hypoplastic and normoblastic and desiccated thyroid not liver extract vitamin B_{12} or pteroylglutamic acid is effective in relieving the anemia Likewise the macrocytic anemia encountered in association with some cases of severe chronic liver disease should not be classed with the megaloblastic macrocytic anemias since the bone marrow is usually normoblastic and a response to liver extract therapy or vitamin B_{12} has been seen only in rare cases //- y

HEMOLYTIC ANEMIAS

Manifestations Under the heading of hemolytic anemias a number of conditions can be included which differ widely in etiology symptomatology severity and course The symptoms depend upon the rapidity and extent of hemolysis its duration and whether or not hemolysis is taking place in the blood stream or in the reticuloendothelial system Jaundice is a sign common to all but its degree may be such as to be barely perceptible (when it is often overlooked) or so great as to be very striking Other symptoms may be entirely absent Thus patients with hereditary spherocytosis are more yellow than sick except when a hemolytic crisis occurs In other cases there may be slowly progressive anemia and gradually increasing jaundice The anemia may become profound and yet there may be few manifestations since in such cases there is time for cardiovascular adjustments (p 202) to be made In chronic hemolytic anemia splenomegaly is common and enlargement of the liver may be present Complications such as gall bladder disease or chronic leg ulcers may develop

On the other hand the onset of hemolytic anemia may be heralded by a severe shaking chill followed by high fever malaise headache and pain in the back abdomen or limbs The abdominal pain may be so severe and may be accompanied by such marked muscular rigidity and spasm as to simulate an acute surgical condition If the hemolysis is rapid and severe enough profound prostration and shock accompanied by anuria and oliguria may ensue When urine is passed it is found to be very dark Jaundice develops rapidly As anemia ensues weakness palpitation dyspnea tachycardia cyanosis cardiac enlargement hemic murmurs vertigo faintness and other manifestations of rapidly developing anemia (Chap 22) make their appearance In certain types of acute hemolytic reactions urticaria vascular disturbances suggesting Raynaud s phenomenon and thrombosis and gangrene may develop

All grades from such acute fulminating disorders of several days duration to extremely benign conditions of many years standing may be encountered A chronic congenital process may be interrupted by acute exacerbations

Hematologic Manifestations The hematologic manifestations which accompany acute blood destruction consist of an initial phase of rapid destruction of red corpuscles and a second phase of rapid blood regeneration These two phases usually overlap especially when the hemolytic agent acts over a prolonged period of time

The anemia may be mild or severe depending upon the intensity and duration of the hemolytic process It is usually normocytic but may be macro

stomach or liver with stomach (USP XIV) and vitamin B_1 –intrinsic factor combinations These should be given in doses of 1 USP unit per day Pteroylglutamic acid (folic acid) 5 to 20 mg daily has also been used in such cases but since it may fail to protect the patient against the development of changes in the nervous system this procedure is not recommended

The diet should be such as to restore the patient to a state of normal nutrition and to maintain him so but need not contain any unusual foods except perhaps where neurologic changes are present In such cases it may be wise to recommend the consumption of say a half pound or more of cooked liver per week This recommendation is made since information is still lacking as to the exact nature of the deficiency which leads to the development of changes in the nervous system By the consumption of whole liver the patient possibly obtains substances of value in addition to the antianemic factor

Transfusion is rarely if ever required in per*nicious anemia since a physiologic response can* be achieved in 48 to 72 hr if vitamin B_1 is given parenterally Since the patient s anemia has developed gradually he has become adjusted to the existent anemia Where the cardiovascular system seems imperfect transfusion by producing a sudden increase in blood volume may sometimes be harmful and may precipitate acute cardiac failure with pulmonary edema Iron is not needed as an adjunct except where iron deficiency exis s as well Supplementary therapy with various vitamins is likewise unnecessary These can be and should be furnished in the diet in the form of food The administration of dilute hydrochloric acid (USP) in amounts of 4 to 8 ml t i d with meals is sometimes of value when gastrointestinal complaints persist particularly eructations or frequent bowel movements In the absence of such complaints hydrochloric acid is unnecessary

Particularly where changes in the nervous system exist confinement to bed should be as brief as possible and the patient should be encouraged to use the limbs even when lying in bed In addition passive movement massage and dry heat are valuable for improving the tone of the muscles Physiotherapy may permit adjustment to permanent damage resulting from the neurologic changes

The development of an intercurrent disease particularly infection calls for an increase in the amount of liver extract or vitamin B_1 therapy since requirements under such conditions seem to be increased

Vitamin B_1 therapy has now essentially replaced treatment with liver extract Even when refined liver extracts were used sensitivity was sometimes observed to develop in the form of severe flushing dizziness a sense of oppression or urticaria following its intramuscular administration Sometimes even peripheral vascular collapse occurred Sensitivity to the crystalline vitamin B_1 is extremely rare

Megaloblastic Macrocytic Anemias Other than Pernicious Anemia

Nutritional Macrocytic Anemia This term refers to macrocytic anemia arising from dietary deficiency as distinguished from deficiency resulting from lack of intrinsic factor or from faulty absorption Since such anemia has been seen most often in the tropics *tropical macrocytic anemia* is another synonym The condition is particularly common in pregnant women Weakness shortness of breath sore mouth sore tongue diarrhea and edema are common complaints In contrast to pernicious anemia in nutritional macrocytic anemia achlorhydria is no more common than in the popu*lation in general and degenerative changes in the* nervous system are practically never found The blood picture and bone marrow are indistinguishable from those of pernicious anemia Tropical macrocytic anemia probably is not a single clinical entity In many cases the anemia has been relieved by the administration of yeast Marmite (autolyzed yeast) or liver In some cases a good hematopoietic response has followed the administration of pteroylglutamic acid and in a few a good response to vitamin B_1 and even to oral penicillin has been reported In certain cases however these agents have not been effective and the need for still an other factor (Wills s factor) has been postulated That some form of dietary deficiency is the cause of this disorder is indicated by the observation that it does not recur if the diet is satisfactory

Nutritional macrocytic anemia is uncommon in the Temperate Zones Few of the instances of macrocytic anemia seen in *pellagra* can be accounted for by a lack of extrinsic factor in the diet In other cases faulty absorption is important and in many both mechanisms play a role In *sprue* and in *idiopathic steatorrhea* as described elsewhere (p 528) inadequate absorption is the main cause for the development of macrocytic anemia In Great Britain in particular *occult idiopathic steatorrhea with* insignificant alimentary symptoms but accompanied by megaloblastic macrocytic anemia is not uncommon This usually responds much better to the administration of pteroylglutamic acid than to vitamin B_1

Macrocytic anemia that occurs following *total gastrectomy* is the consequence of lack of intrinsic factor The absorption of orally administered vitamin B_1 has been shown to be impaired The patho

genesis of the macrocytic anemia seen in association with *intestinal structures* and *anastomoses* has been attributed to impaired absorption but the fact that good hematopoietic responses have been observed when Aureomycin or Terramycin was given makes plausible the thesis that the anemia is caused by the colonization of the small intestine by abnormal bacteria which in some way divert folic acid or vitamin B_{12} from the host

The available evidence suggests that vitamin B_{12} and folic acid act as coenzymes at different stages in the biologic synthesis of nucleoproteins (p 1176) and that a deficiency of either or both results in a number of abnormalities of which megaloblastic bone marrow is the most readily recognized Under certain circumstances dietary deficiency of folic acid may develop and result in nutritional macrocytic anemia In other patients there may be defective absorption of folic acid (sprue idiopathic steatorrhea) but in some such patients the absorption of vitamin B_{12} may be impaired as well In still other cases alterations in the gastrointestinal tract may lead to consumption or destruction of one or both of these substances or an antimetabolite may be produced there (fish tapeworm anemia intestinal strictures and anastomoses) Only following total gastrectomy is absorption of vitamin B_{12} impaired in a manner corresponding to that encountered in pernicious anemia i e as the result of lack of intrinsic factor Various combinations of defects in dietary content absorption consumption destruction or antagonism may result in various degrees of deficiency of vitamin B_{12} or folic acid or both In addition it has been postulated that vitamin B_{12} in some manner influences the storage absorption and utilization of folic acid and that when vitamin B_{12} is lacking these functions are impaired

Quite unexplained are the more than a dozen instances of megaloblastic macrocytic anemia which have been observed in patients undergoing anticonvulsant therapy with either diphenylhydantoin sodium or Promidone Prohibition of the anticonvulsant particularly when associated with administration of folic acid resulted in complete relief of the anemia

Although macrocytic anemia is seen in some cases of hypothyroidism it is noteworthy that the bone marrow is hypoplastic and normoblastic and desiccated thyroid not liver extract vitamin B_{12} or pteroylglutamic acid is effective in relieving the anemia Likewise the macrocytic anemia encountered in association with some cases of severe chronic liver disease should not be classed with the "megaloblastic" macrocytic anemias since the bone marrow is usually normoblastic and a response to liver extract therapy or vitamin B_{12} has been seen only in rare cases

HEMOLYTIC ANEMIAS

Manifestations Under the heading of hemolytic anemias a number of conditions can be included which differ widely in etiology symptomatology severity and course The symptoms depend upon the rapidity and extent of hemolysis its duration and whether or not hemolysis is taking place in the blood stream or in the reticuloendothelial system Jaundice is a sign common to all but its degree may be such as to be barely perceptible (when it is often overlooked) or so great as to be very striking Other symptoms may be entirely absent Thus patients with hereditary spherocytosis are "more yellow than sick" except when a hemolytic crisis occurs In other cases there may be slowly progressive anemia and gradually increasing jaundice The anemia may become profound and yet there may be few manifestations since in such cases there is time for cardiovascular adjustments (p 202) to be made In chronic hemolytic anemia splenomegaly is common and enlargement of the liver may be present Complications such as gall bladder disease or chronic leg ulcers may develop

On the other hand the onset of hemolytic anemia may be heralded by a severe shaking chill followed by high fever malaise headache and pain in the back abdomen or limbs The abdominal pain may be so severe and may be accompanied by such marked muscular rigidity and spasm as to simulate an acute surgical condition If the hemolysis is rapid and severe enough profound prostration and shock accompanied by anuria and oliguria may ensue When urine is passed it is found to be very dark Jaundice develops rapidly As anemia ensues weakness palpitation dyspnea tachycardia cyanosis cardiac enlargement hemic murmurs vertigo faintness and other manifestations of rapidly developing anemia (Chap 22) make their appearance In certain types of acute hemolytic reactions urticaria vascular disturbances suggesting Raynaud s phenomenon and thrombosis and gangrene may develop

All grades from such acute fulminating disorders of several days duration to extremely benign conditions of many years standing may be encountered A chronic congenital process may be interrupted by acute exacerbations

Hematologic Manifestations The hematologic manifestations which accompany acute blood destruction consist of an initial phase of rapid destruction of red corpuscles and a second phase of rapid blood regeneration These two phases usually overlap especially when the hemolytic agent acts over a prolonged period of time

The anemia may be mild or severe depending upon the intensity and duration of the hemolytic process It is usually normocytic but may be macro-

cytic especially during the stage of rapid regeneration when many relatively immature and reticulated cells are present It is not uncommon to find 10 to 25 per cent reticulocytes in chronic cases and as many as 60 per cent or even more in acute cases Polychromatophilia nucleated red blood corpuscles and Howell Jolly bodies are usually present There generally is marked variation in the size of the cells (anisocytosis) and usually little variation in their shape (poikilocytosis) except in patients with sickle cell anemia Spherocytes may be numerous

Marked stimulation of the leukopoietic tissues manifested by leukocytosis and a shift to the left with myelocytes and even rare myeloblasts accompanies the red corpuscle regeneration Platelets may increase in number and large bizarre forms may make their appearance In certain cases however and especially in paroxysmal nocturnal hemoglobinuria leukopenia and thrombocytopenia may be present

The *bone marrow* is hyperplastic There is a great increase in normoblasts and a consequent reduction in the leukocyte/erythrocyte ratio from the normal of 4 or 5 1 to about 1 1 or even less The normoblasts are chiefly polychromatophilic and orthochromatic forms as a rule there are not many pronormoblasts or basophilic normoblasts Megaloblasts so characteristic of pernicious anemia and related macrocytic anemias are not present

Pigment Metabolism When the degree and rate of blood destruction are very great hemoglobin is liberated into the plasma and if the hemoglobin binding capacity of the plasma (haptoglobin p 199) is exceeded free hemoglobin is excreted by the kidneys and hemoglobinuria results However the finding of red urine must not be assumed to be necessarily indicative of hemoglobinuria The color may also be produced by intact red corpuscles porphyrin or myoglobin Microscopic and spectroscopic examination of the urine will reveal the cause of the abnormal color Under certain circumstances hematin (p 199) may be released

More often blood destruction is less rapid In such cases hemoglobinemia and hemoglobinuria are not found and there is only an increase in the icterus index serum bilirubin and urobilinogen excretion in the urine and feces The stools assume a dark color and from 300 to 4 000 mg urobilinogen may be found in a 24 hr stool as compared with the normal of 40 to 280 mg The 24 hr urine may contain 5 to 200 mg urobilinogen (normal 0 to 3 5 mg) The fecal urobilinogen may be increased when the urine urobilinogen and the bilirubin in the blood are not significantly greater than normal

The quantity of bilirubin in the plasma may rise as high as 10 mg per cent The reaction is indirect but some increase in direct or "one minute" bilirubin (bilirubin glucuronide) may also occur The intensity of the bilirubinemia depends not only on the extent of the blood destruction but also on the capacity of the liver to remove the pigment from the blood stream and excrete it in the bile A normally functioning liver is capable of excreting large quantities of bilirubin but as anemia and consequent hypoxemia develop its functional capacity becomes impaired and bilirubin accumulates in the blood stream

Classification

The hemolytic disorders may be classified in various ways none of which is entirely satisfactory A clinical classification based on the severity of the manifestations may be confusing since a chronic process may come to notice only during an acute exacerbation Differentiation of congenital and acquired forms is useful Better still however is classification on the basis of pathogenesis even though understanding of the pathogenesis of the hemolytic anemias is still incomplete

By transfusing corpuscles which differ from those of the recipient with respect to their MN or Rh type or by giving group O corpuscles to recipients belonging to one of the other three major blood groups it has been shown that when normal corpuscles are transfused to patients in whom there is an extracorpuscular cause for hemolysis the donated corpuscles are destroyed as rapidly as the patient s own corpuscles If on the other hand the patient s corpuscles are removed from their abnormal environment and transfused to a normal recipient their survival time is normal Hemolytic anemias which have been shown to be or are thought to be of this type are listed in group I of Table 101 Group II includes disorders in which hemolysis is the result of a defect in the patient s own red corpuscles The patient s corpuscles when given to a normal recipient can be shown to be disposed of more rapidly than those of the recipient while the latter s corpuscles if transfused into the patient maintain a normal life span It may be noted that in the main hemolytic anemias due to intracorpuscular defects are familial and hereditary while those produced by extracorpuscular factors are acquired

Acute Hemolytic Anemias Due to Immune Body Reactions The naturally occurring agglutinins α and β cause hemolysis when incompatible blood is given by transfusion When hemolytic transfusion reactions take place in spite of A B and O blood group compatibility they are attributable in most instances to the development of anti Rh (D) agglutinins Next in frequency are the Kell antigen and antibody Other blood groups are only rarely involved (p 418) Such agglutinins are also responsible for the development of hemolytic disease of the newborn (*erythroblastosis fetalis*) a condi

tion in which the red corpuscles of an Rh positive fetus are destroyed as the result of the action of antibodies produced in the Rh negative woman carrying the fetus

Although the number of possible causes of hemolytic anemia is large as Table 101 indicates in a very significant number of cases of acquired hemolytic anemia no cause is found and no associated disease is recognized *Idiopathic cases* have been observed at all ages from five months to seventy eight years but females are more often affected than males The clinical manifestations range in the extremes The course may be acute severe and fulminating or the illness may be insidious in onset and chronic in course In the latter instances repeated attacks of greatly exaggerated blood destruction may punctuate the course and may be followed by spontaneous remissions By and large the manifestations are rarely as mild as they may be in hereditary spherocytosis The hematologic features are similar to those of other hemolytic anemias varying according to the severity of the condition In most instances however certain immunologic manifestations may be demonstrated if they are looked for The introduction of serologic methods like the Coombs test has made possible the demonstration of antibodies in the majority of cases of idiopathic acquired hemolytic anemia

There appear to be several varieties of idiopathic acquired hemolytic anemia They are in part associated with differences in the type of antibody which is found In the majority a "warm" antibody is present i e the antibody reacts well at 37 C and is not potentiated at lower temperatures The most common warm antibodies are incomplete that is they sensitize normal erythrocytes to antiglobulin serum but do not cause agglutination in a saline medium The sensitization is not inhibited by previous heat inactivation of the patient s serum at 56 C and it is increased only slightly by acidification of the serum to pH 6 5 or 7 Typically these warm antibodies cause agglutination and not hemolysis The sensitizing antibodies usually are γ globulins

"Cold" antibodies are markedly potentiated by reducing the temperature below 37 C These antibodies are "incomplete" antibodies but they may also act as "complete" agglutinating antibodies and under certain circumstances may also bring about hemolysis Two main forms of cold antibodies have been demonstrated in acquired hemolytic anemias The common typical type is a powerful antigen the rare variety is similar to the Donath Landsteiner antibody of paroxysmal cold hemoglobinuria In cases of acquired hemolytic anemia associated with the presence of cold antibodies cyanosis and Raynaud s phenomenon on exposure to cold as well as hemoglobinuria may be noted Spherocytes are

Table 101 CLASSIFICATION OF HEMOLYTIC DISORDERS

- I Extracorpuscular causes
  - A Acute hemolytic anemias due to immune body reaction
    - 1 Isoagglutinins anti A anti B (transfusion reactions)
    - 2 Isoagglutinins anti Rh anti Hr Kell Duffy etc (hemolytic disease of the newborn intra group transfusion reactions)
    - 3 Cold hemolysins (paroxysmal cold hemoglobinuria)
  - *B* Idiopathic acquired hemolytic anemias
  - *C* Secondary or symptomatic hemolytic anemias
    - 1 Hodgkin s disease
    - 2 Chronic lymphocytic leukemia lymphosarcoma
    - 3 Disseminated lupus erythematosus
    - 4 Metastatic carcinomatosis
    - 5 Dermoid cysts
    - 6 Liver disease
    - 7 Thrombotic thrombocytopenic purpura
  - *D* Infectious agents
    - 1 Malaria
    - 2 *Bartonella* (Oroya fever)
    - 3 Septicemia *Clostridium welchii Vibrio comma* (cholera) rarely others
    - 4 Viruses (atypical pneumonia infectious mononucleosis)
  - *E* Chemical agents
    - 1 Related to size of dose
      - *a* Phenylhydrazine
      - *b* Naphthalene
      - *c* Trinitrotoluene
      - *d* Benzene
      - *e* Acetanilid
      - *f* Phenacetin
      - *g* Aniline
      - *h* Methyl chloride
      - *i* Arsine
      - *j* Lead
    - 2 Depending on hypersensitivity
      - *a* Sulfonamides
      - *b* Quinine
      - *c* Pamaquine
      - *d* Primaquine
      - *e* p-Aminosalicylic acid
      - *f* Benzedrine
      - *g* Mesantoin
      - *h* Paraphenylenediamine
  - *F* Physical agents (heat—severe thermal burns)
  - *G* Vegetable and animal poisons
    - 1 Vegetable poisons
      - *a* Fava bean (*Vicia faba*)
      - *b* Castor bean (ricin)
    - 2 Animal poisons
      - *a* Snake venoms
- II Intracorpuscular defects
  - A Hereditary spherocytosis (familial or congenital hemolytic jaundice)
  - *B* Hereditary elliptocytosis
  - *C* Hereditary nonspherocytic hemolytic anemias
  - *D* Hereditary leptocytosis (thalassemia Mediterranean anemia)
  - *E* Sickle cell disease
  - *F* Other hereditary hemoglobinopathies (C D E G H I J K)
  - *G* Combinations of thalassemia and sickle-cell disease or other hemoglobinopathies
  - *H* Paroxysmal nocturnal hemoglobinuria

cytic especially during the stage of rapid regeneration when many relatively immature and reticulated cells are present It is not uncommon to find 10 to 25 per cent reticulocytes in chronic cases and as many as 60 per cent or even more in acute cases Polychromatophilia nucleated red blood corpuscles and Howell Jolly bodies are usually present There *generally is marked variation in the size of the cells* (anisocytosis) and usually little variation in their shape (poikilocytosis) except in patients with sickle cell anemia Spherocytes may be numerous

Marked stimulation of the leukopoietic tissues manifested by leukocytosis and a "shift to the left" with myelocytes and even rare myeloblasts accompanies the red corpuscle regeneration Platelets may increase in number and large bizarre forms may make their appearance In certain cases however and especially in paroxysmal nocturnal hemoglobinuria leukopenia and thrombocytopenia may be present

The *bone marrow* is hyperplastic There is a great increase in normoblasts and a consequent reduction in the leukocyte/erythrocyte ratio from the normal of 4 or 5 1 to about 1 1 or even less The normoblasts are chiefly polychromatophilic and orthochromatic forms as a rule there are not many pronormoblasts or basophilic normoblasts Megaloblasts so characteristic of pernicious anemia and related macrocytic anemias are not present

Pigment Metabolism When the degree and rate of blood destruction are very great hemoglobin is liberated into the plasma and if the hemoglobin binding capacity of the plasma (haptoglobin p 199) is exceeded free hemoglobin is excreted by the kidneys and hemoglobinuria results However the finding of red urine must not be assumed to be *necessarily indicative of hemoglobinuria* The color may also be produced by intact red corpuscles porphyrin or myoglobin Microscopic and spectroscopic examination of the urine will reveal the cause of the abnormal color Under certain circumstances hematin (p 199) may be released

Classification

The hemolytic disorders may be classified in various ways none of which is entirely satisfactory A clinical classification based on the severity of the manifestations may be confusing since a chronic process may come to notice only during an acute exacerbation Differentiation of congenital and acquired forms is useful Better still however is classification on the basis of pathogenesis even though understanding of the pathogenesis of the hemolytic anemias is still incomplete

By transfusing corpuscles which differ from those of the recipient with respect to their MN or Rh type or by giving group O corpuscles to recipients belonging to one of the other three major blood groups it has been shown that when normal corpuscles are transfused to patients in whom there is an extracorpuscular cause for hemolysis the donated corpuscles are destroyed as rapidly as the patient s own corpuscles If on the other hand the patient s corpuscles are removed from their abnormal environment and transfused to a normal recipient their survival time is normal Hemolytic anemias which have been shown to be or are thought to be of this type are listed in group I of Table 101 Group II includes disorders in which hemoly*sis is the result of a defect in the patient s own* red corpuscles The patient s corpuscles when given to a normal recipient can be shown to be disposed of more rapidly than those of the recipient while the latter s corpuscles if transfused into the patient maintain a normal life span It may be noted that *in the main hemolytic anemias* due to intracorpuscular defects are familial and hereditary while those produced by extracorpuscular factors are acquired

Acute Hemolytic Anemias Due to Immune Body Reactions The naturally occurring agglutinins α and *β cause hemolysis* when incompatible blood is given by transfusion When hemolytic transfusion reactions take place in spite of A B and O blood group compatibility they are attributable in most instances to the development of anti Rh (D) agglutinins Next in frequency are the Kell antigen and antibody Other blood groups are only rarely involved (p 418) Such agglutinins are also responsible for the development of hemolytic disease of the newborn (*erythroblastosis fetalis*) a condi

molysins have been described as already mentioned Immune hemolysins are not found free in the serum except in disorders which require special conditions for their maximum operation Thus in paroxysmal cold hemoglobinuria a fall in temperature is required for maximum activity of the hemolytic system while in paroxysmal nocturnal hemoglobinuria a fall in the pH of the blood is necessary In most instances immune hemagglutinins remain attached to the red corpuscle The Coombs or "developing" test serves to demonstrate such factors (p 1186)

The role of mechanical factors is indicated by the fact that the osmotic and mechanical fragilities of the red corpuscles increase when the corpuscles are placed in natural or artificial immune serums in which hemolysins and agglutinins are present Similar changes in fragility have been observed in association with the action of hemolytic agents such as saponin or physical factors such as heat Osmotic lysis usually determined by the familiar hypotonic saline fragility test probably does not operate in vivo except perhaps in the spleen under certain conditions It is a plausible hypothesis that mechanical trauma is the ultimate mechanism whereby cell destruction occurs under normal circumstances and in many varieties of hemolytic anemia It has been shown that nearly spherical cells strongly agglutinated cells and those with weakened cell membranes are abnormally susceptible to mechanical destruction In certain cases of acquired hemolytic anemia increased mechanical fragility has been observed when osmotic fragility was normal It was found that such cells did not survive normally in the circulation of normal individuals The increased mechanical fragility of sickled masses of erythrocytes may explain the increased red corpuscle destruction in sickle-cell anemia

The term *erythrostasis* has been applied to the processes to which red corpuscles are subjected when denied free access to fresh plasma The spleen appears to have the property of selectively removing and concentrating spheroidal cells Erythrostasis may lead to increased osmotic and mechanical fragility of the red corpuscles and thereby favor their destruction It has been suggested that the spleen is of importance in congenital hemolytic jaundice because of the inherently abnormal susceptibility of the red corpuscles to the effects of erythrostasis It has been demonstrated that in a patient with congenital hemolytic jaundice who had received transfusions of identifiable normal corpuscles the spleen removed at operation, had selectively retained the patient s own corpu cles Perfusion experiments have shown that even the spleen from a case of purpura hemorrhagica where no hemolytic process ex1 ted likewise selectively removed transfused red corpuscles from cases of congenital hemolytic jaundice but did not retain normal corpuscles

Sequestration in the spleen and also in the liver plays an important role in acquired hemolytic anemias In sequestering sensitized red corpuscles from the circulation the spleen behaves as a highly proficient passive filter Thus it has been shown that when sensitized red corpuscles are injected in the circulation of normal subjects they are agglutinated by the plasma globulins following which they are sequestered in the spleen and are hemolyzed within a few minutes The speed of the hemolysis is such as to suggest the presence of a preformed lysin leukocytes may be involved in this lytic process However in contrast to the fate of these sensitized corpuscles coated with "incomplete" antibodies in reactions involving "complete" antibodies as when red corpuscles are injected into normal subjects hyperimmunized against them sequestration and destruction occur in the liver to a greater extent than in the spleen

Studies of spontaneous hemolysis of red corpuscles in vitro (autohemolysis) have led to the recognition of a metabolic defect in the red corpuscles of hereditary spherocytosis The continued presence of glucose during incubation of the red corpuscles was observed to retard markedly the potassium loss and the increase in osmotic fragility of the cells It was possible to demonstrate that abnormalities in the dynamics of intracellular carbohydrate metabolism exist Thus using radioactive phosphorus as a tracer it was found that in cells from patients with hereditary spherocytosis there is a smaller flux of P^{32} into adenosinetriphosphate and 2 3 diphosphoglyceric acid than in normal cells and a concurrent increase in the flux into orthophosphate It was shown also that in many instances the metabolic lesion could be reversed with adenosine and glucose Thus some of the deleterious effects of erythrostasis can be explained An adequate rate of supply of energy rich phosphate bonds is necessary for the maintenance of the biconcave shape of the red corpuscle Energy production may be defective as the result of genetically controlled enzyme deficiencies or functional inadequacies Such red corpuscles are less well able to maintain their integrity than normal ones

Study of a Patient with a Hemolytic Disorder

Hemolytic anemia can be recognized by the development of certain symptoms and signs certain changes in the blood and bone marrow and characteristic alterations in pigment metabolism as already outlined The differentiation of the various hemolytic disorders is important since treatment depends on their nature The history alone may suffice to reveal an etiologic agent or may indicate that one is dealing with one of the familial or

not conspicuous and osmotic fragility may be normal The course of these cases is generally chronic and often is relatively mild They most commonly occur in elderly persons

In addition to these warm and cold autoantibodies it is not uncommon to find other manifestations of abnormal protein formation in patients with *acquired hemolytic anemia Thus antibodies against* lipoid antigens may be present and may give rise to false positive Wassermann and Kahn reactions This is especially frequent in disseminated lupus erythematosus Again serum complement may be reduced and hypergammaglobulinemia and cryoglobulins may develop

It was assumed at first that the autoantibodies found in acquired hemolytic anemia were nonspecific that is they reacted with all types of human red cells without relation to any known blood group antigens In some cases however the autoantibodies have been found to be specific and were directed against various Rh antigens and more rarely against other blood groups such as Kell B and O The serology of the acquired hemolytic anemias is complicated however Autoantibodies without apparent specificity have been observed in the same blood as those in which specific antibodies were discovered Furthermore it has been observed that the antibodies of one patient often differ considerably from those of another in temperature requirements specificity chemical nature and in their reactions in vitro A few cases have been described in which the patients serums contained *a potent agglutinin for enzyme treated cells* but this was not associated with a positive direct Coombs test In cases in which cold antibodies have been demonstrated there has not been a clear correlation between their titer and hemolysis or such exposure to cold as might be expected to lead to agglutination and subsequent mechanical destruction of the red corpuscles

Certain features serve to distinguish chronic hemolytic anemia with erythrocyte bound antibody from other types of hemolytic anemia As already indicated warm or cold hemagglutinins are present and the Coombs test (p 1186) is positive Spherocytosis is usually marked when the disease is active and at such times the osmotic fragility of the red corpuscles is irregularly increased and their mechanical fragility is also increased Even normal transfused cells become spherical their fragility becomes increased and they are rapidly destroyed In quiescent stages however the spherocytosis may be absent and osmotic and mechanical fragility may be normal

It has been pointed out that oxalated blood from patients with hemolytic anemia associated with immune bodies may have a granular appearance when examined with a hand lens as the blood is allowed to flow in a thin layer along the side of a glass container In rare cases this may even be seen with the naked eye The phenomenon is attributable to the agglutination of the red corpuscles in the plasma

Other Hemolytic Anemias Presumably Due to Extracorpuscular Causes The clinical manifestations of the hemolytic anemias associated with various disorders (symptomatic hemolytic anemias) are similar to those in cases of the idiopathic variety except for the presence of manifestations of the underlying disease The latter however are sometimes not apparent and must be sought out carefully *Although it was at first thought that erythro*cyte bound antibodies do not develop in cases of symptomatic hemolytic anemia with the introduction of appropriate serologic techniques it is becoming clear that at least a great proportion of these cases are of the immune body type

Table 101 lists the large variety of infectious chemical and physical agents which may be associated with the development of hemolytic anemia Of the chemical agents some such as saponin act directly on the red corpuscles Others depend for their action on an abnormality of the host (sensitivity) It has been shown that there is an intrinsic abnormality in the red corpuscles of persons sensitive to sulfanilamide acetanilid phenacetin naphthalene primaquine phenylhydrazine thiazolsulfone (Promizole) sulfoxone (Diasone) and nitrofurantoin (Furadantin) The abnormality consists in a reduced glutathione content and defective en*zymatic protection against damage by one of these* drugs This appears to be due to reduced glucose 6 phosphate dehydrogenase activity in the sensitive cells There is evidence that the sensitivity to the fava bean which results in the development of hemolytic anemia (*favism*) depends on a similar mechanism The red cell abnormality in these sensitive persons differs from that seen in disorders classified in Table 101 under the general heading of Intracorpuscular Defects such as hereditary spherocytosis in that the red cell abnormality of sensitive persons per se has no known deleterious effect on the individual or on the red cell life span *in the absence of the offending chemical agent*

Intracorpuscular Defects A number of the disorders coming under this head are described separately below

Mechanisms of Hemolysis Various processes condition or cause the destruction of red *corpuscles* phagocytosis agglutinins and hemolysins *osmotic* lysis mechanical factors and sequestration with erythrostasis The importance of phagocytosis is not clear Some regard it as a primary and important factor *while others relegate it to an accessory role dependent on other mechanisms* of red corpuscle destruction Various types of hemagglutinins and he

Table 102 COOMBS TEST

Hemolytic disorder	Antihuman globulin serum mixed with patient's RBCs (*direct*)	Antihuman globulin serum mixed with normal RBCs after incubation in patient's serum (*indirect*)	
		RH+	*RH−*
Acquired hemolytic anemia			
With circulating antibodies	+	+	+
Without circulating antibodies	+	−	−
Due to Rh antibodies in Rh+ infant (erythroblastosis fetalis)	+	+	−
Due to physical or chemical agents	±	−	−
Congenital hemolytic anemia (hereditary spherocytosis)	−	−	−
Sickle-cell anemia	−	−	−
Paroxysmal nocturnal hemoglobinuria	−	−	−
Paroxysmal cold hemoglobinuria (type associated with syphilis)	+	−	−

The occasional finding of a positive Coombs test in this and in other hemolytic anemias where the test is usually negative is explained by superimposed frequently transient episodes of acquired hemolytic anemia

glutinin and the treatment of the red corpuscles with proteolytic enzymes such as papain and trypsin which renders them more susceptible to the demonstration of antibodies For the antibody tests it is necessary in some instances to use the patient's own red corpuscles rather than any available group O red corpuscles as is often the practice

Prognosis and Treatment Prognosis and treatment *depend on the nature and cause of the hemolytic disorder* The causative agent such as a parasite or chemical if discovered must be removed An acute attack of hemolysis requires rest maintenance of fluid balance and relief of pain Blood transfusion may be dangerous if the cause of the hemolysis is extracorpuscular and still operating for then the introduced blood may also be destroyed Yet when blood destruction is so acute that hemoglobinemia and hemoglobinuria are present the possibility of death from circulatory collapse is so great that frequent and sometimes massive blood transfusions must be given

An important advance in the management of many cases of acquired hemolytic anemia is the discovery that the administration of adrenocorticotropic hormone (ACTH) or of prednisone or cortisone will control the hemolytic manifestations The latter are preferable since they can be given orally As much as 60 to 100 mg prednisone or 200 to 400 mg cortisone per 24 hr may be required In some instances transfusion can be withheld entirely while in other cases where the anemia is so severe that transfusion is necessary blood can be given with much less chance of a reaction if cortisone or ACTH therapy has been started As in the treatment of other disorders the usual precautions such as salt restriction and *administration of potassium chloride* should be taken when these agents are used in the treatment of hemolytic anemia

Splenectomy while almost invariably beneficial in hereditary spherocytosis is much less successful in the acquired forms Furthermore if carried out in an acute hemolytic phase the operative mortality is high In idiopathic acquired hemolytic anemia *therefore the hormones should be used first* at least in preparation for operation Unfortunately neither splenectomy nor hormone therapy is permanently helpful in all cases in many the evidence of hemolysis returns when hormone therapy is interrupted

In some cases of "symptomatic hemolytic anemia treatment of the underlying disorder when possible relieves the hemolytic anemia as well When this does not occur a trial of steroid therapy is justified In certain instances splenectomy may be helpful especially if leukopenia and thrombocytopenia are also present and the picture is that of hypersplenism

Splenectomy is of no value in sickle cell anemia thalassemia or paroxysmal nocturnal hemoglobinuria

Paroxysmal Cold Hemoglobinuria

This is an uncommon disorder characterized by the sudden passage of hemoglobin in the urine following local or general *exposure to cold* Aching and pain in the back legs or abdomen and other symptoms of acute hemolysis such as a chill fever and malaise are associated with the passage of dark brownish urine Other findings are those characteristic of acute hemolytic anemia Symptoms may

hereditary disorders Physical examination may reveal one of the conditions of which hemolytic anemia can be symptomatic In addition certain simple tests have been devised which give some clue to the nature of the disorder

Osmotic Fragility Test In certain cases of hemolytic anemia one demonstrates by this test the susceptibility of red corpuscles to hemolysis in concentrations of salt which fail to cause rupture of normal corpuscles Such osmotic fragility is characteristic of corpuscles which are more nearly spherical than normal corpuscles The test is generally positive in hereditary spherocytosis and negative in acquired forms Unfortunately however there are exceptions to this statement Spherocytosis and increased osmotic fragility are encountered in certain acquired cases especially in an acute phase The sensitivity of the test can be increased by first incubating the corpuscles to be tested in vitro at body temperature for 24 hr Under such conditions the fragility of normal corpuscles is increased slightly that of corpuscles from cases of hereditary spherocytosis is increased markedly and symmetrically

Mechanical Fragility Test A small amount of oxalated or defibrinated blood is placed in an Erlenmeyer flask containing glass beads and rotated following which the hemoglobin liberated from the cells is measured and compared with controls Increased mechanical fragility has been observed in congenital hemolytic jaundice in sickle cell anemia and in the presence of cold agglutinins and isoagglutinins after agglutination of the cells in the cold as well as in a few cases of atypical hemolytic anemia in which osmotic fragility was normal or decreased

Serologic Tests A simple presumptive test is performed by placing washed red corpuscles from fresh defibrinated blood in each of three test tubes The first is incubated for 1 to 2 hr at body temperature and then centrifuged If hemoglobin is present in the supernatant serum the presence of a *warm hemolysin* is suggested The second tube is chilled for 20 min in cracked ice then incubated for 1 hr and centrifuged If the result is positive the presence of a *cold hemolysin* is indicated The test tube should be examined before it has been warmed If only *cold agglutinins* are present and no hemolysins it will be seen that the red corpuscles agglutinate in the cold but fail to hemolyze when the tube is warmed the clumps disappearing instead When cold agglutinins are present one must be careful not to shake the cells too much while they are agglutinated in the cold since they may hemolyze and give a false cold hemolysin test The blood placed in the third tube is acidified with carbon dioxide If hemolysis is apparent after incubation for 1 hr and subsequent centrifugation *increased acid hemolysis* is suggested This test is positive in paroxysmal nocturnal hemoglobinuria

When positive results are obtained in any one of these tubes the test should be repeated with adequate controls and by the more complete procedures which are available Thus if a cold hemolysin appears to be present, the Donath Landsteiner test should be carried out

The *Coombs antiglobulin test* as already indicated has proved to be very valuable in helping to clarify the heterogeneous group of acquired hemolytic anemias The *direct" Coombs test* is carried out simply by mixing the patient s washed red cells with serum from rabbits immunized to human gamma globulin and examining the mixture for agglutination It serves to demonstrate the presence of "incomplete" antibodies that is those which are attached at some points on the surface of the red corpuscles and require a completing substance such an antihuman globulin to cause an agglutination reaction to take place A positive result has been observed in cases of idiopathic acquired hemolytic anemia in that type of paroxysmal cold hemoglobinuria which is associated with syphilis and in many instances of "symptomatic" hemolytic anemia The test has been negative in most cases of hereditary spherocytosis and is generally negative in sickle cell anemia and in paroxysmal nocturnal hemoglobinuria but in hemolytic anemia due to various physical or chemical agents it has sometimes been positive

A positive "direct Coombs test is also observed when isoimmunization to known immune bodies has occurred as in hemolytic disease of the newborn and in sensitization following transfusion The indirect test serves to differentiate such antibodies In the indirect test antihuman globulin serum is mixed with normal group O Rh positive and Rh negative red corpuscles which have been incubated in the patient s serum The resulting reactions are shown in Table 102 If agglutination occurs with both Rh positive and Rh negative cells Rh antibodies can be excluded

In performing the Coombs test it is important that potent antiserum be used and adequate controls carried out False negative results may occur if the red corpuscles have not been washed sufficiently or as a result of a prozone reaction due to inadequate dilution of the serum Cold hemagglutinins may cause a false positive reaction

The detailed elucidation of a case of hemolytic anemia of the antibody type will often require the use of still other procedures but these in the main are quite simple They include the setting up of agglutination tests at various temperatures and in several media such as isotonic sodium chloride solution and bovine albumin solution these are helpful in demonstrating and characterizing the ag

iron pigment are found in the liver kidneys and even lymph nodes

Symptoms Jaundice and splenomegaly are the most common manifestations and may pass un noticed for many years A persistent sallow appear ance rather than obvious jaundice may be present Symptoms of anemia are usually absent or mild At any time from birth to late adult life attention may be drawn to the disorder by the *crise de déglobu lisation* which is characterized by fever lassitude palpitation and shortness of breath or even violent abdominal pain vomiting and anorexia Rather than being episodes of increased blood destruction as has always been assumed these crises have been observed by several investigators to be associated with sudden temporary cessation of blood formation Since the life span of the red corpuscles of con genital hemolytic icterus is very brief anemia de velops rapidly under these circumstances It re mains to be shown how often such a mechanism rather than hemolysis is the cause of the crises which occur in this disease It has been suggested that both mechanisms play a role and that both are manifestations of hypersplenism"

The liver may or may not be enlarged Develop mental anomalies are often present A chronic leg ulcer may be found Cholelithiasis is a frequent complication and symptoms due to this cause may first bring the patient to the physician

The anemia is usually moderate in degree but may be very mild or severe It is normocytic or simple microcytic in type but when severe and as sociated with marked reticulocytosis it can be macrocytic There is little poikilocytosis but small bright deeply staining red corpuscles (spherocytes) are often seen scattered among the cells of normal size Reticulocytes are characteristically increased in number most often numbering 5 to 20 per cent Polychromatophilia and normoblasts may be seen in the blood smear The leukocytes are usually nor mal in number or slightly increased The platelet count is generally normal

Increased osmotic fragility of the red corpuscles is characteristic Hemolysis beginning at 0 64 per cent saline solution is not unusual and may be complete at the point where hemolysis normally begins

Bilirubinemia of the indirect type and increased quantities of urobilinogen in the urine and stools without bile in the urine (acholuric) are the characteristic changes in pigment metabolism

Diagnosis Splenomegaly icterus of the hemo lytic type reticulocytosis increased osmotic fragil ity and demonstration of the anomaly in other members of the family are the characteristic find ings The Coombs test is negative except in occa sional cases In these it is likely that a superimposed acquired immunohemolytic process has developed When the picture is not entirely typical a careful study to rule out other types of hemolytic anemia must be made as outlined previously

It is especially important to distinguish cases of *congenital nonspherocytic hemolytic anemia* be cause they have not been benefited by splenectomy Although such cases resemble hereditary sphero cytosis in their mode of inheritance they differ in that the anemia is generally macrocytic there is often a moderate degree of ovalocytosis and some times there is conspicuous punctate basophilia Spherocytes are not found and osmotic fragility is normal The reported cases have not been identical in all respects however and probably represent several different disorders This statement is based on observation of morphologic differences such as the presence of crenated and irregularly contracted corpuscles in some cases Pappenheimer bodies in others extreme variation in red cell size and shape in still others as well even as increased resistance to saline hemolysis and the presence of target cells as in instances of certain abnormal hemoglobin dis orders It has been shown that the reversibility of the metabolic lesion by adenosine observed in certain cases of hereditary spherocytosis did not occur in congenital nonspherocytic hemolytic ane mia Studies of autohemolysis have revealed at least two forms of the nonspherocytic disorder

Treatment This is the one disorder in which splenectomy is associated with consistently satis factory results The operation is indicated in every patient in whom clinical manifestations are present Although remissions develop and latent periods of many years duration may occur spontaneous recov ery does not take place At operation a careful search should be made for accessory spleens and they should be removed if found Following opera tion anemia jaundice and reticulocytosis disap pear The osmotic fragility of the red corpuscles however as well as the spherocytosis may persist

During a crisis repeated blood transfusions must be given

SICKLE CELL ANEMIA AND OTHER ABNORMAL HEMOGLOBIN SYNDROMES

Definition Sickle cell anemia is a hereditary and familial hemolytic anemia essentially peculiar to Negroes and characterized by the presence of red corpuscles which under appropriate conditions as sume sickle shaped or oat shaped forms

Etiology and Pathogenesis Just as hereditary spherocytosis is rare in the Negro sickle cell ane mia is extremely rare except in Negroes or when mixture with Negro blood has occurred The anom aly appears to be inherited as a mendelian dominant characteristic Inheritance of the abnormality from only one parent the heterozygous state is repre-

appear at any time from a few minutes to 7 or 8 hr following exposure

Donath and Landsteiner showed that the hemoglobinuria is due to the sudden intravascular hemolysis of blood as the result of the action of an autohemolysin contained in the patient's blood The hemolysin unites with the red corpuscles only at a low temperature but destruction of the corpuscles occurs only after the temperature of the blood has returned to body temperature Appropriate tests have been devised to demonstrate such a cold hemolysin At the time of hemolytic attacks produced by chilling strongly positive direct antiglobulin (Coombs) reactions have been observed but they become negative after the attacks The typical condition is a manifestation of syphilis the congenital form particularly and thorough antisyphilitic therapy ends the clinical manifestations

A number of cases have been described however in which indications of syphilis were lacking even though the Wassermann reaction was *positive* In view of the fact that false positive Wassermann and Kahn reactions are not uncommon in acquired hemolytic anemia of the autoantibody type it has been suggested that paroxysmal cold hemoglobinuria is not exclusively a manifestation of syphilis and that some of the cases regarded as the typical condition of syphilitic origin may well have been examples of autoimmune hemolytic disease of the cold antibody type

Chronic Hemolytic Anemia with Paroxysmal Nocturnal Hemoglobinuria (Marchiafava Micheli Syndrome)

This is a rare disorder of insidious onset which is characterized by signs of hemolytic anemia and is marked by attacks of hemoglobinuria which occur chiefly at night The symptoms are those of long standing anemia but there may be abdominal lumbar or substernal pain which often ushers in an attack of hemoglobinuria The findings are similar to those in other hemolytic anemias and include splenomegaly and well marked anemia The osmotic fragility of the red corpuscles is normal and spherocytosis is not characteristic There may be hemoglobinemia even when there is no hemoglobinuria Leukopenia is usual and may be marked and there may be thrombocytopenia The urine contains increased amounts of urobilinogen as well as hemoglobin Hemosiderin can often be demonstrated in the leukocytes or epithelial cells of the urine

The fault appears to reside in the red corpuscles which are unusually susceptible to acid hemolysis A simple test for this has been described already (p 1186) It has been suggested that the destruction of the cells is promoted by the accumulation of carbon dioxide during sleep an optimum acid pH being required for hemolysis to take place The latter has been shown to be brought about by the action of the *properdin system* The components of this system are properdin (a protein) Mg^{++} and cofactors resembling complement all of which are normal constituents of plasma Normal human red cells are not damaged by this system The defect in PNH (paroxysmal nocturnal hemoglobinuria) red corpuscles which renders them susceptible to the properdin system may possibly reside in the lipid pattern of the lipoproteins of their stroma

This disorder does not appear to be hereditary Treatment is purely symptomatic Splenectomy is of no value The intensity of the hemolytic process varies and crises of severe anemia may occur Transfusion of plasma usually precipitates hemolytic crises but fortunately saline washed red corpuscles can be given with impunity Although thrombocytopenia is common purpuric or hemorrhagic manifestations are unusual in fact thrombotic complications are not infrequent It has been found that *the anticoagulant dicoumarin (Dicumarol) impedes* hemolytic activity in this disease but this drug is chiefly of importance in order to prevent thrombotic complications Infections are frequent in these patients partly perhaps because of the associated leukopenia Prognosis varies greatly Although a fatal termination may ensue in several years in some cases the disorder has been compatible with life for many years

Hereditary Spherocytosis (Chronic Acholuric Jaundice Spherocytic Anemia Chronic Familial Icterus Congenital Hemolytic Jaundice)

Definition This is a familial and hereditary disorder characterized by spherocytosis increased osmotic fragility of the red corpuscles splenomegaly and a variable degree of hemolytic anemia

History Chiefly as the result of the observations of the French school during the early part of the present century this familial disorder was clearly defined becoming known as the type of Chauffard and Minkowski It was distinguished from the acquired form of hemolytic anemia of Hayem and Widal

Etiology Transmitted as a mendelian dominant by either parent this disorder is due to an inherited defect of the red corpuscles which tend to be more spheroid than normal and thus are more subject to destruction The significance of spheroidicity of the red corpuscles and of increased osmotic fragility and the role of the spleen have been discussed already (p 1184)

Morbid Anatomy The spleen is greatly enlarged often weighing 1 000 to 1 500 Gm The pulp and to a lesser extent the sinuses are greatly congested Depending on the degree of anemia and the extent of blood destruction hyperplasia and even metaplasia of the bone marrow occur and deposits of

[1] The major hemoglobin component is shown first. In sickle-cell anemia especially there may also be a substantial proportion of Hb F.
[2] Osmotic fragility is reduced more or less proportionately to the number of target cells.
[3] Mechanical fragility and RBC survival correspond *as a rule* to the presence and degree of hemolytic anemia.
[4] Chiefly in Negroes.
[5] Cases of sickle-cell anemia intermediate in severity between sickle-cell trait and sickle-cell anemia.
[6] Sickle-cell disease in Caucasians.
[7] Or polycythemia with microcytosis.
[8] Basophilic stippling of the red corpuscles.
SOURCE Wintrobe, Clinical Hematology, 4th ed, Philadelphia, Lea & Febiger, 1956.

with S hemoglobin is accompanied by sickling of the red corpuscles as well as by a hemolytic syndrome similar to sickle cell anemia but differing in that the hemolytic anemia is milder, target cells are more plentiful in the blood, and there is slowly progressive splenomegaly. It is very probable that most of the cases formerly reported as representing forms of sickle cell anemia intermediate between the asymptomatic carrier state and the homozygous classical disease actually were cases simultaneously heterozygous for S and C hemoglobin.

Hemoglobin D is very rare. *Hemoglobin E* has been found in approximately 13 per cent of the population of Thailand and has been encountered frequently in association with the gene for thalassemia. *Hemoglobin G* has been found in Negroes in West Africa and in a family of Italian origin. *Hemoglobin H* was described in a Chinese family and in a Greek family and has also been observed in Thailand. *Hemoglobin I* has been identified in a Negro family. *Hemoglobin J* and *K* have also been reported. In Table 103 some of the hematologic characteristics associated with the inheritance of the various abnormal hemoglobins are indicated and the clinical manifestations associated with the homozygous states and various gene combinations are also outlined.

Sickle cell anemia was first described in Negroes

sented by the sickle cell trait in which sickling of the red corpuscles can be demonstrated but is not accompanied by symptoms of anemia Sickle cell anemia is the homozygous state in which one abnormal gene has been inherited from each parent Sickle cell anemia possesses all the characteristics of a chronic hemolytic anemia with certain special features as well

From time to time exception has been taken to the heterozygous homozygous theory described above because of certain family studies which failed to demonstrate the sickle cell trait in both parents of children with sickle cell anemia and also because certain cases were observed which seemed to be intermediate in their clinical manifestations between those of the severe hemolytic anemia of sickle cell anemia and the asymptomatic state the sickle cell trait The discovery of abnormal hemoglobins other than sickle cell hemoglobin has offered a reasonable explanation for these exceptions as will be described shortly

The discovery by Pauling and his associates that the electrophoretic mobilities of sickle cell anemia (S) and normal hemoglobin (A) differ led to establishment of the principle that a molecular abnormality in a single protein may cause a sequence of events such as that which characterizes the complex disease sickle cell anemia It was shown that in a buffer of suitable pH the two components of a mixture of normal and sickle cell hemoglobin migrate in opposite directions On the basis of the difference in their isoelectric points it was concluded that the hemoglobin of sickle cell anemia has two to four more net positive charges per molecule than normal hemoglobin Since the heme moiety is the same in sickle cell and in normal hemoglobin the electrophoretic differences have been attributed to differences in the folding or coiling of the polypeptide chains thus either bringing into play or removing from action charged groups and thus indirectly altering the electrophoretic behavior of the proteins

The ratio of sickle cell hemoglobin to normal hemoglobin in the blood of individuals with the sickle cell trait has been found to vary from 22 to 45 per cent while the amount in the blood of those with sickle cell anemia has varied from 76 to 100 per cent The variations in the amount of sickle cell hemoglobin have been explained on the ground that the expression of the S gene may be under the modifying influence of other genetic factors the lower and higher proportions of S hemoglobin are a familial characteristic

Hemoglobin S is relatively insoluble The sickling process seems to be best explained on the assumption that in the oxygen unsaturated state the S hemoglobin molecule undergoes orderly orientation forming by specific linkage of the individual molecules long chains of hemoglobin elements Subsequent parallel alignment of these elements results in birefringent tactoids the sickled cell being a hemoglobin tactoid thinly veiled and somewhat distorted by the cell membrane The clinical and hematologic manifestations and the pathologic changes found in sickle cell anemia can be explained by the peculiar physical properties of the sickle cell The intracellular molecular orientation produces the sickled form of the erythrocyte At decreased oxygen tensions the viscosity of the whole blood and the mechanical fragility of the erythrocytes are significantly increased owing to the assumption of the sickled form With the increase in viscosity a cycle is initiated in which the factors of stasis lowered pH and continuing oxygen uptake combine to augment the number of sickled cells and prolong the stasis Plugs or masses of sickled erythrocytes become solid enough to occlude vessels and result in the "thrombotic episodes associated with pain which are characteristic of the disease Erythrostasis limits access to cell maintaining energy and also favors the sickled state When red cells after stasis are released into free circulation a certain proportion having been fixed in irreversible sickled form have also become more fragile in terms of mechanical trauma Consequently they are more than normally susceptible to the trauma associated with circulation Increased blood destruction is the result The development of these changes depends on the quantity of abnormal hemoglobin present it is assumed that in the homozygous state the erythrocytes contain sufficient abnormal hemoglobin to result in sickling within the physiologic range of oxygen tensions It is of interest that although the heterozygous state is ordinarily benign splenic infarction has been observed in a number of instances in persons with the sickle cell trait who were subjected to conditions of greatly reduced oxygen tension

Hemoglobin C is the name given to a third type of adult hemoglobin so named to distinguish it from *hemoglobin A* normal adult hemoglobin and *hemoglobin S* sickle cell hemoglobin The incidence in the United States of the gene responsible for C is about 2 per cent in the Negro population as compared with about 9 per cent for S hemoglobin

Carriers of hemoglobin C are asymptomatic but target red corpuscles are found characteristically in their blood The homozygous (CC) state is characterized by the presence of a normocytic hemolytic anemia of mild degree or no anemia whatsoever More than two dozen instances of homozygous hemoglobin C disease have been reported all in Negroes with but two exceptions

In addition a number of instances have been discovered in which both S and C hemoglobin were demonstrated The combination of hemoglobin C

Etiology Those first discovered to be affected were chiefly of Italian Greek Syrian or Armenian parentage In certain communities of Italians the anomaly has been observed in as many as 4 per cent of those examined The disorder is due to the inheritance of a factor which leads to an anomaly of red corpuscle production While there is in this condition a disturbance in iron metabolism the primary defect appears to be in hemoglobin synthesis It has been found that the red corpuscles in this disorder contain a variable and often large proportion of fetal hemoglobin as indicated by the high resistance of the hemoglobin to denaturation in aqueous alkaline solutions as well as by other physical properties In the severe form of the disease the electrophoretic pattern of the hemoglobin resembles a mixture of normal and fetal hemoglobin This has led to the suggestion that the gene governing this disorder blocks the production of normal hemoglobin and causes the production of fetal hemoglobin as a compensatory phenomenon The mode of inheritance seems to be that of a recessive In the heterozygous state when only one allele is inherited (thalassemia minor) the interference with hemoglobin synthesis is not serious In the homozygous condition when two alleles are inherited one from each parent (thalassemia major) there is a drastic reduction in normal hemoglobin production

The discovery of the high incidence of thalassemia in Thailand where it is said to be the most common form of hemolytic anemia and the report of thalassemia minor in the Sikh community in Vancouver Canada as well as in the Chinese and other Orientals has led to the suggestion that the thalassemia trait was carried from a large area in the Mediterranean Basin along the routes of the early migration of races

Symptomatology The full blown disorder (*thalassemia major Cooley s anemia*) develops insidiously within the first year or two of life perhaps at birth and is marked by pallor and great enlargement of the spleen and even the liver The appearance of the child is often mongoloid Roentgenograms reveal great thickening of the diploe of the skull with perpendicular striation increase in the medullary portion of the long bones with thinning of the cortex and other changes attributable to the extreme hyperplasia of the bone marrow Anemia is severe hypochromic and microcytic in type and the red corpuscles contain so little pigment and are so thin that their "buckling produces forms which have the appearance of targets Fragility tests in hypotonic saline solutions reveal that the corpuscles are unusually resistant to hemolysis by this means Normoblasts and microblasts as well as polychromatophilia basophilic stippling Howell Jolly bodies and moderate reticulocytosis in addition to leukocytosis (19 000 to 25 000 per cubic millimeter) with "shift to the left reflect the myeloid hyperactivity There is usually slight or moderate bilirubinemia with a corresponding increase in the urobilinogen content of the urine and stools

Thalassemia minor on the other hand may pass entirely unnoticed since painstaking examination may be necessary to reveal any abnormality Slight anemia splenic enlargement microcytosis and hypochromia target cells poikilocytosis out of proportion to the existent anemia decreased hypotonic saline fragility basophilic stippling of the red corpuscles and bilirubinemia are some of the signs which singly or in various combinations mark this disorder Roentgenographic changes in the bones similar to though less pronounced than those found in the severe form may be observed

The degree of penetrance of the thalassemia gene seems to vary greatly or there are modifying factors There is such a wide range in the manifestations of the heterozygous condition that some investigators have attempted to classify the Mediterranean hemopathic syndrome in a number of different groups The term *thalassemia minima* refers to those instances in which the manifestations are very slight In some persons the number of red corpuscles is actually increased above normal although since the red corpuscles are usually microcytic and hypochromic the hemoglobin and volume of packed red cells are usually slightly below the average normal values

Microdrepanocytic disease is the name given to the combination of sickle cell and thalassemia genes which results in a chronic hemolytic anemia with some of the characteristics of both sickle cell disease and thalassemia The thalassemia trait has also been observed in association with hemoglobin C hemoglobin E and other hemoglobins Some of the clinical and hematologic manifestations of these combinations have been outlined in Table 103

Diagnosis Plumbism congenital hemolytic jaundice and sickle cell anemia are among the disorders which must be distinguished on the basis of the characteristics already described

Prognosis The severe form is fatal and seems to be more grave the earlier it becomes manifest Less severe forms are compatible with life and the mildest forms may even have no influence whatever on life span

Treatment With the exception of the rare forms of hypochromic microcytic anemia which were discussed earlier (p 1174) this is the only form of hypochromic microcytic anemia in man which does not respond to iron therapy Splenectomy is of no value nor are any other measures now known

Pathology Evidences of pronounced myeloid hyperplasia both medullary and extramedullary the effects of such changes on the bones and de

in North America In Africa there is a broad belt of high incidence of the sickling trait which extends roughly across the middle third of the continent the highest figures being in eastern and central Africa The sickling trait however does not seem to be present exclusively in the Negroes of Africa or in Negroes of African origin It has been discovered in certain aborigines in southern India and in southern Arabia as well as in Greece and in southern Turkey However the homozygous condition sickle cell anemia is very rare in the white race Instances of sickle cell anemia which have hitherto been described in white persons have been in those of Greek or Italian stock These cases it now appears are examples of admixture of the sickling and the thalassemia traits and are not instances of the homozygous sickle cell disease

Pathology In addition to the signs of a chronic *hemolytic anemia (normoblastic hyperplasia of the* bone marrow hemosiderosis) evidence of thrombosis infarction necrosis) or hemorrhage may be present especially in the lungs spleen and nervous system The spleen may be shrunk to a tiny wrinkled mass

Symptoms Jaundice and a chronic anemia with few or no complaints are interrupted by periods of increased weakness episodes of aching pain in the joints or elsewhere in the extremities or sudden attacks of severe abdominal pain which have often been mistaken for ruptured peptic ulcer intestinal obstruction or some other abdominal emergency

The victims of sickle cell anemia are often poorly developed and bony deformities of various types may be discovered The scleras are icteric and there may be slight general glandular enlargement but splenomegaly is encountered in only about 15 to 20 per cent of cases The heart may be enlarged and the physical signs may closely simulate those of mitral stenosis due to rheumatic fever Hyposthenuria is common In many instances chronic leg ulcers are found over the internal or external malleoli Roentgenograms may reveal radial striation in the skull osteoporosis in the vertebral bodies or other changes in the long bones Osteomyelitis is a not infrequent complication

The anemia is usually surprisingly severe erythrocyte counts below 2 5 million being common The anemia may be normocytic or macrocytic Oval cigar shaped or other bizarre forms of red corpuscles may be seen in the stained blood smear The sickling is brought out clearly in wet films of blood which have been fixed under a cover glass and sealed with paraffin In cases with sickle cell anemia the typical sickled and oat shaped forms with elongated pointed filaments appear within a few hours When only the sickle cell trait exists 24 hr is often required to produce *this change* and only a proportion rather than practically all of the cells are affected By the use of reducing agents such as sodium bisulfite sickling can be hastened and the characteristic forms appear promptly

In sickle cell anemia reticulocytosis polychromatophilia normoblasts leukocytosis with shift to the left" in the myeloid series and an increase in platelets are found as well as hyperbilirubinemia and increased urobilinogen in the urine and stools Osmotic fragility is decreased not increased The bone marrow shows striking normoblastic hyperplasia

Diagnosis Sickle cell anemia is often mistaken for some other disease *Rheumatic fever* peptic ulcer renal or biliary calculus osteomyelitis and various neurologic disorders may be simulated Recognition depends on the demonstration of sickling and the finding of anemia of the hemolytic type

In distinguishing persons with the sickle cell trait who may have some disorder accompanied by anemia from those who have sickle cell anemia it must be kept in mind that the former may develop any type of anemia while in the latter the anemia is always hemolytic in type

The distinguishing features of the other hemoglobinopathies and of disorders resulting from combinations of the sickle cell gene with the genes for other abnormal hemoglobins or with the thalassemia gene are presented in Table 103 For the exact identification of the abnormal hemoglobins paper electrophoresis and the alkali denaturation procedure for fetal hemoglobin are necessary

Treatment There is no satisfactory treatment Splenectomy is of no value Blood transfusion may be helpful in the abdominal crisis if shock is present The disease is ultimately fatal often before the age of thirty

THALASSEMIA (Cooley s Anemia Erythroblastic Anemia Mediterranean Anemia Target-cell Anemia Familial Microcytic Anemia)

Definition An inherited disorder seen particularly in individuals living in countries bordering the Mediterranean or in their offspring elsewhere which is characterized by the presence of unusually thin red corpuscles microcytosis various degrees of anemia and when the anemia is severe numerous nucleated red corpuscles There is also a high incidence in Thailand

History Cooley and Lee (1925) described a chronic progressive anemia commencing early in life which was associated with a *characteristic* facies splenomegaly and a *familial and racial* incidence Later it became clear that this was the *severe* and fatal form of a disorder which in milder form is seen in adolescents and in adults

As already described the anemia of *iron deficiency* is hypochromic microcytic in type and that due to lack of anti pernicious anemia principle and related substances is macrocytic *Protein deficiency* is characterized by the presence of normocytic anemia Deficiencies of the various B vitamins are rarely encountered in man in pure form Multiple nutritional deficiencies are associated as a rule with only moderate anemia usually normocytic in type

ANEMIAS ASSOCIATED WITH INFECTIONS AND VARIOUS OTHER DISORDERS CHIEFLY CHRONIC

In the preceding sections anemia resulting from blood loss as well as anemias due to excessive blood *destruction* and *those associated with deficiency* of certain factors concerned in erythropoiesis were discussed The characteristics of these anemias are in the main well defined and much has been learned in recent years about their pathogenesis The hemolytic anemias and the specific nutritional deficiency anemias are however relatively uncommon Far more frequent in occurrence and yet *much less well understood are the anemias associated* with various chronic disorders and with infection Such anemia is usually only moderate in degree hemoglobin values of 13 to 10 Gm per 100 ml of blood are seen more frequently than lower values The anemia is usually normocytic and in the smear the red corpuscles generally show little abnormality in size or shape a monotonous picture unaccompanied by polychromatophilia basophilic stippling or nucleated red corpuscles Exceptions are found in *lead poisoning* where basophilic stippling *is characteristically seen* in the so called *myelophthisic anemias* such as those associated with metastases to the bone marrow leukemia multiple myeloma or myelosclerosis and in severe *renal disease* There often corresponding rather closely to the gravity of the renal disorder as manifested by the degree of retention of nitrogenous and other waste products hemoglobin values as low as 5 Gm per 100 ml are found and the blood smear may reveal normoblasts stippling and moderate anisocytosis and poikilocytosis The anemia may be somewhat microcytic or hypochromic and occasionally is macrocytic If the renal disease has been insidious in onset and is chronic in type the clinical manifestations and the anemia may be quite confusing unless one is aware that striking degrees of anemia may be encountered in the absence of impressive signs of renal disorder

The *bone marrow* in these conditions shows nothing characteristic The nucleated red corpuscles are of the normoblastic type The marrow may appear hyperplastic normal or hypoplastic *Hyperplasia of the leukopoietic* tissue is found if the disorder is one which calls forth a leukocytic response

The *pathogenesis of the anemia in these conditions* has been discussed elsewhere (p 201) It seems likely that some fault in the construction of red corpuscles is an important *underlying mechanism* in their development In any event the impact of infection on erythropoiesis is such that no form of antianemic therapy such as the administration of vitamin B_{12} or of iron has any influence The anemia disappears spontaneously if the infection is successfully treated or subsides as the result of the defense reactions of the host Similarly *the anemia of renal insufficiency is closely tied with* the underlying disorder and is generally not influenced by measures other than those which affect *renal function*

It is both interesting and curious therefore that the oral administration of *cobaltous chloride* in doses ranging from 20 to 160 mg per day generally in the form of 20 mg size enteric coated tablets taken with meals has been observed to produce a modest reticulocytosis and a significant moderation in the degree of anemia both in cases of anemia *accompanying chronic infection* and *in that associated* with renal disease In the latter appetite may improve and there may be increased tolerance for the medications necessary to correct electrolyte abnormalities There is no evidence that cobalt therapy alters the course of renal disease and the hemoglobin has been found to return to pretreatment levels after cobalt administration has been discontinued *The mode of action of cobalt is obscure* but it is generally assumed that it serves as a nonspecific erythropoietic stimulant rather than as a specific nutritional component required for red cell or hemoglobin production

Malignant disease is not necessarily accompanied by anemia Anemia accompanies malignancy in the alimentary tract more often than elsewhere In such cases nutritional deficiency may play an important role in the pathogenesis of the anemia and in many cases blood loss is also a contributory factor Malignant disease of the kidneys breast prostate thyroid and lungs in particular may metastasize to bones and in such an event "*myelophthisic anemia* may develop *The picture then may be that of* a pancytopenia (see p 1210) or a leukemoid picture may result The latter is marked by leukocytosis together with a moderate *shift to the left* in the leukocytic formula and normocytic anemia When a number of nucleated red corpuscles also appear in the peripheral blood as they sometimes do the term *leukoerythroblastic* anemia appropriately describes what is found The pathogenesis of myelophthisic anemia was discussed briefly elsewhere (p 202)

Endocrine insufficiency may be associated with anemia Hypothyroidism is often accompanied by anemia of moderate degree This is usually normocytic but can be macrocytic (p 210) Slight or moderate anemia usually normocytic is found in Addison s disease and in pituitary insufficiency (*Simmonds disease*)

History Vaquez in 1892 described a case of polycythemia which he had originally attributed to congenital heart disease Osler gave a more complete description in 1903

Etiology and Pathogenesis None of the recognized causes of erythrocytosis already discussed in Chap 12 (p 98) appears to play a role in this disorder It appears usually in middle or late life Familial cases have been described

Since oxygen want is known to produce polycythemia hypoxemia of the bone marrow has been proposed as the fault underlying the development of erythremia Not only is there no demonstrable bone marrow hypoxia in erythremia but this hypothesis ignores the fact that the increase in red corpuscles is but a part of a generalized myeloid hyperplasia which may be manifested in leukocyte counts as high as 60 000 per cubic millimeter and an increase in platelets A close relationship to chronic myelocytic leukemia is suggested by such cases A failure of hematopoietic balance can also be postulated but unfortunately the factors which regulate and maintain the blood at "normal" are unknown

Pathology The striking changes are those related to the increase in total blood volume All the organs are engorged with blood the veins stand out like bunches of thick worms and there may be thromboses or anemic infarcts The *bone marrow* is dark red in color and very cellular Microscopically this is found in most instances to be due to hyperplasia of all the marrow elements In some cases the percentage of normoblasts is increased in others the proportions of myelocytes and myeloblasts or of basophilic and eosinophilic cells may be greater than normal

The *spleen* is enlarged chiefly from hyperplasia of the pulp and distention with blood Infarcts are common There may be foci of extramedullary blood formation in the spleen the liver and occasionally elsewhere as well Cirrhosis of the liver has been observed in a number of instances

Symptomatology The onset is insidious and the progress gradual Headache dizziness ringing in the ears or visual disturbances dyspnea lassitude or weakness skin or mucous membrane hemorrhages a sense of weight in the abdomen due to the enlargement of the spleen or irritability depression forgetfulness or vague symptoms suggesting neurasthenia are complaints encountered in many cases Various gastrointestinal symptoms such as fullness belching or constipation may be present or symptoms of peptic ulcer may be found Sometimes the symptoms are those attributable to increased metabolism lassitude increased sweating and loss of weight Swelling and pain in the extremities may be very troublesome In still other cases the symptoms are so insignificant that the polycythemia is discovered only accidentally

The face is a deep red rather than truly cyanotic The color is most noticeable in the lips cheeks tip of the nose ears and neck The distal portions of the extremities may be more truly cyanotic since the highly viscous blood circulates more sluggishly there than is normal Ecchymoses are common and epistaxis and bleeding of the gums are frequently encountered Cardiac abnormality is unusual but vascular disturbances are common These include venous thromboses coronary thrombosis and cerebrovascular accidents The blood pressure is more often normal than elevated Enlargement of the liver is frequent and splenomegaly is found in at least 75 per cent of cases The spleen may be just palpable or it may extend even to the pelvic brim

Blood Erythrocyte counts of 7 to 10 million cells per cubic millimeter are common Unless hemorrhage has occurred or venesections have been performed there is a corresponding increase in hemoglobin and in volume of packed red corpuscles The individual red corpuscles appear normal although occasional polychromatophilia or basophilic stippling may be noted The finding of nucleated red corpuscles and the appearance of small numbers of myelocytes and even earlier forms in the blood give a clue to the hyperplastic state of the bone marrow leukocytosis sometimes of marked degree (60 000 per cubic millimeter) due to an increase of the granulocytes and high platelet counts when present give further evidence of overactivity The percentage of reticulocytes is not increased unless there has been recent bleeding The osmotic fragility of the red corpuscles is not significantly altered There may be some evidence of increased blood destruction in the form of slight bilirubinemia and increased excretion of urobilinogen The viscosity of the blood is greatly increased even five to tenfold The thick sticky blood may be slow to coagulate and the clot may not retract Bleeding and clotting times are usually normal however

The total blood volume is substantially increased (150 to 300 per cent of normal) entirely because of an increase in red corpuscle mass

Other Laboratory Findings These include increased basal metabolic rate in many cases normal increased or reduced gastric secretion even achlorhydria and normal urine or slight proteinuria

Diagnosis The symptoms of erythremia alone may suggest a variety of disorders but once the blood has been examined the problem is to differentiate secondary forms of polycythemia (*erythrocytosis*) from the primary disorder (see p 99) Failure to discover a cause for the polycythemia and the presence of a reddish rather than bluish cyanosis favor the diagnosis of erythremia

213 ERYTHREMIA (Polycythemia Rubra Vera)

M M Wintrobe

Definition Erythremia also known as Vaquez or Osler s disease or splenomegalic polycythemia is a disease of unknown etiology and of insidious onset and slow chronic course It is characterized by a striking absolute increase in the quantity of circulating red corpuscles and often by evidence of increased production of myeloid leukocytes and even of platelets Splenomegaly and a red cyanosis of the skin as well as increase in the viscosity of the blood and in the total volume of the blood are additional features of this disorder

as soon as it is formed The exact nature of this mechanism is not understood

Etiology *Hereditary* or *familial methemoglobinemia* is a rare condition approximately 100 cases have been reported in the literature The mode of inheritance is unknown Both sexes are affected although there is a preponderance of male victims All the families described have been of the white race and individuals of Greek stock have predominated Cyanosis without associated clubbing of the fingers is present from birth and methemoglobin comprises 20 to 50 per cent of the total hemoglobin A compensatory polycythemia is frequently observed The disease is rarely fatal and most of the patients reach an advanced age A number of patients with *congenital methemoglobinemia* have been reported without a familial history of the disease and a few patients with *idiopathic methemoglobinemia* have been observed in whom the congenital nature of the disease was not clearly demonstrated In patients with one of the above forms of methemoglobinemia the normal cellular mechanism for reducing methemoglobin is absent

Secondary methemoglobinemia is more common than hereditary or congenital methemoglobinemia and is caused by contact with drugs containing amino or nitro groups (Table 104) These drugs preferentially oxidize hemoglobin and in sufficient amounts overcome the normal reducing mechanism of the erythrocytes In secondary methemoglobinemia unlike what happens in the hereditary or congenital forms of the condition the oxygen dissociation curve is shifted to the left and the unloading of oxygen in the tissues is seriously handicapped (Chap 12) When exposure to the offending drug ceases the methemoglobin is rapidly converted to the reduced compound and the cyanosis disappears Nitrates after ingestion may be converted to nitrites by intestinal bacteria and after absorption from the intestine produce methemoglobin Cases of methemoglobinemia due to nitrates or nitrites have been reported following the use of bismuth subnitrates or of ammonia or potassium nitrate from the therapeutic use of amyl nitrite or nitroglycerin from food high in nitrates in infants drinking well water high in nitrates from the inhalation of nitrous gases by arc welders and by the ingestion of corning syrup Aniline dyes may produce methemoglobinemia by penetration of the infant skin Contact with dyed blankets laundry marks on diapers and freshly dyed shoes has produced methemoglobinemia The ingestion by children of certain red wax crayons containing p nitroaniline has resulted in methemoglobinemia The commonly dispensed analgesic and antipyretic drugs acetanilid and phenacetin are aniline derivatives and have frequently been found responsible

for methemoglobinemia Certain sulfonamides such as sulfanilamide Prontosil sulfathiazole and sulfapyridine but not sulfadiazine or sulfamerazine produce the condition

Enterogenous cyanosis is a term used to refer to a clinical syndrome characterized by attacks of cyanosis headache abdominal pain with either diarrhea or constipation dyspnea dizziness collapse and syncope Many of the patients reported were taking aniline derivatives for headache It has been suggested that because of the gastrointestinal disease there was an abnormal production and absorption of nitrites Sulfhemoglobinemia has been present frequently together with methemoglobinemia in the blood of these patients

In addition to the above types of methemoglobinemia rare cases of acquired hemolytic anemia with paroxysmal methemoglobinemia have been reported

Clinical Manifestations When as little as 1 5 Gm of methemoglobin is present in 100 ml of blood recognizable cyanosis results In contrast about 5 Gm of reduced hemoglobin must be present before a comparable degree of cyanosis occurs Since methemoglobin is incapable of combining with oxygen the symptoms of methemoglobinemia are attributable to the hypoxia produced by the lowered oxygen capacity of the blood The severity of the

Splenomegaly is very unusual in erythrocytosis even when the erythrocyte count is very much increased What is more in the latter condition leukocytosis immature leukocytes and an increase in the platelet count are hardly ever found and normoblasts are much more uncommon in the blood than in erythremia

An absolute increase in red corpuscle mass is found in erythrocytosis as well as in erythremia Measurement of blood volume therefore does not aid in differentiating secondary polycythemia but because of variations in plasma volume it is a truer index of the degree of polycythemia than the hematocrit level It is also helpful in the occasional patient often a heavily built middle aged and sometimes hypertensive male in whom there is only relative polycythemia (stress erythrocytosis) Measurement of arterial oxygen saturation is useful in differentiating erythrocytosis due to cardiac or pulmonary disease for in the latter oxygen saturation is reduced more or less in inverse proportion to the degree of polycythemia whereas in erythremia it is normal or nearly normal

Course and Complications Barring the development of serious complications the course of erythremia adequately treated is chronic and the disorder is often compatible with many years of life The most dangerous complications are vascular thrombosis or hemorrhage Therapy by keeping the red corpuscle mass at a nearly normal level can effectively reduce blood viscosity and thus serves to reduce the likelihood of such vascular accidents Intercurrent infections especially of the respiratory tract may be troublesome and bronchitis and emphysema may develop Peptic ulcer and hypertension are frequent complications and less often gout and cirrhosis of the liver The development of typical chronic myelocytic leukemia in a number of cases of erythremia has given support to the view that there may be a close relationship between these two disorders

Treatment Treatment is symptomatic since the cause of erythremia is unknown Symptomatic relief is best achieved by reducing the red corpuscle mass to something approaching normal This is most quickly achieved by *venesection* Approximately a pint of blood is removed twice a week or even more often until the volume of packed red corpuscles approaches normal Then the procedure may need to be repeated only once a month or less often *Phenylhydrazine hydrochloride* though now rarely used is effective in destroying the red corpuscles but it is best first to use venesection to lower the blood level to normal subsequently giving only enough of the hemolytic agent to maintain the blood at normal For this purpose 0 1 Gm in capsules once a day every other day or every third day should be adequate The use of such small doses will avoid complications of phenylhydrazine therapy such as thrombosis and acute hemolytic anemia This drug should not be used for bed ridden patients or for those who have thrombosis already

Instead of removing or destroying the excessive red corpuscles hematopoiesis may be inhibited by irradiation or by nitrogen mustard therapy The effects of *irradiation* are slow to appear however and consequently venesection must be used at the same time initially The *intravenous injection of* radioactive phosphorus (P^{32}) is more satisfactory than roentgen therapy The procedure depends on the fact that the radioactive phosphorus passes to tissues which have a high phosphorus content The concentration of P^{32} in the bones places this agent in a strategic position Usually 3 to 5 millicuries of P^{32} is given After 10 to 12 weeks if symptomatic and hematologic improvement are inadequate a second dose is administered Subsequent therapy is "titrated" according to need but intervals between injections should not be shorter than 10 weeks and leukocyte and platelet counts should be included in the blood examinations as guides in avoiding marrow aplasia from overdosage Remissions of 6 to 10 months are common but much longer ones are not unusual

Although agents such as nitrogen mustard and triethylenemelamine have been shown to be effective in the treatment of erythremia they offer no advantages over radioactive phosphorus while their toxic effects scarcely justify their use if P^{32} is available

214 METHEMOGLOBINEMIA, SULFHEMOGLOBINEMIA

George E Cartwright

METHEMOGLOBINEMIA

Methemoglobin is an oxidation product of hemoglobin which cannot function as an oxygen carrier Under normal circumstances 98 to 99 per cent of the hemoglobin in the erythrocytes is in the reduced state (ferrohemoglobin) and 1 to 2 per cent is in the oxidized state (ferrihemoglobin or methemoglobin) The reduced hemoglobin is constantly being converted to methemoglobin but some mechanism within the cells reduces the methemoglobin

215 THE PURPURAS

M M Wintrobe

Definition The term *purpura* refers to extravasations into the skin or mucous membranes They may vary from the size of a pin point or slightly bigger (petechiae) to much larger areas (ecchymoses) Purpura is but one manifestation of abnormal bleeding already discussed (p 214)

THROMBOCYTOPENIC PURPURA

Definition This term refers to purpura which is accompanied by a significant reduction in the platelet count There is at the same time prolongation of bleeding time a positive tourniquet test and poor clot retraction but the coagulation time and prothrombin time are normal The purpura may be *essential* or *primary* this also being known as *purpura hemorrhagica* or *Werlhof's disease* or it may be symptomatic the effect of various chemical vegetable animal or physical agents the accompaniment of certain infections or a part of the picture of various blood disorders

History Werlhof in 1735 distinguished purpura hemorrhagica as an entity distinct from the purpuric manifestations of various pestilential fevers and differing from other hemorrhagic disorders Denys noted the thrombocytopenia in 1887 while Kaznelson proposed treatment by splenectomy in 1916

Etiology and Pathogenesis Purpura hemorrhagica occurs most frequently in children and in young adults and is somewhat more common in the female than in males No more than 10 per cent of cases begin after the age of forty Not infrequently there is a family history of excessive bleeding The condition is rare in Negroes

In the bone marrow the number of megakaryocytes is normal or may even be increased However in contrast to the normal picture few or no platelets are found about their margins Moreover also significant is the fact that splenectomy is often followed by striking improvement These observations have led to the assumption that this disorder is caused by (1) a decreased rate of formation of platelets from megakaryocytes as the consequence of splenic inhibition (2) platelet destruction by the spleen or (3) a combination of damage to both megakaryocytes and circulating platelets perhaps through the action of a humoral factor in the plasma That the last is true in many cases probably as the result of an immunologic mechanism is indicated by studies in which platelet agglutinins were shown to be present in the plasma of patients with essential thrombocytopenic purpura It was also demonstrated that the injection of plasma from patients with this disease into normal recipients was associated with thrombocytopenia bleeding phenomena and alterations in the megakaryocytes Furthermore transfused platelets disappear with extraordinary rapidity from the circulation of patients with acute idiopathic thrombocytopenic purpura It is plausible to assume that the spleen removes sensitized platelets and may also produce some of the platelet agglutinin

Platelet agglutinins were first described in patients with thrombocytopenic purpura due to Sedormid In these cases it was shown that the drug forms an antigenic complex with the platelets to which an antibody is formed It is possible that in "idiopathic" thrombocytopenic purpura an unidentified toxin affects both platelets and capillary endothelium which are antigenically similar and that an antibody to these damaged tissues is produced

That there is in addition to thrombocytopenia a defect in the capillary endothelium is suggested by the fact that hemorrhage in this disease is not always closely correlated to the degree of platelet reduction It has been proposed that the capillaries are unusually permeable or that they are incapable of adequate contraction For the latter hypothesis evidence has been presented which is based on direct observation

The *prolonged bleeding time* is explained by a failure of the capillaries to retract as well as by the lack of sufficient platelets to plug the opening of a bleeding vessel The intracutaneous oozing of blood when capillary pressure is increased (tourniquet test) is explained in the same way Coagulation time is normal because few platelets are needed to initiate clotting The clot however is loose and retracts poorly because a large number of platelets are needed for syneresis

Symptomatology Purpura hemorrhagica may begin abruptly and disappear spontaneously just as suddenly or its manifestations may seem to have been present a long time occasionally so long that they might appear to be characteristic of the individual concerned The bleeding may be mild with perhaps only inconspicuous purpuric spots in the skin or it may be severe and not only may lead to serious loss of blood but also may occur into vital areas such as the cranium or the diaphragm All variations between these extremes may be encountered and the disorder may wax and wane in intensity Acute and chronic forms of the disorder have been described and by some investigators are regarded as different entities It is not unusual for symptoms first to become apparent following an acute infection

The lesions in the skin usually consist of minute red hemorrhages which differ from telangiectases

symptoms is related to the quantity of methemoglobin present the rapidity with which the methemoglobinemia develops and the capacity of the individual's cardiorespiratory and hematopoietic systems to adjust to the hypoxia In general levels of less than 20 per cent methemoglobin are usually not associated with symptoms At levels of 20 to 50 per cent fatigue weakness dyspnea tachycardia headaches and dizziness may occur Only rarely is enough methemoglobin present to cause coma and death

Diagnosis Methemoglobinemia should be suspected in any patient with intense cyanosis especially if physical examination fails to reveal evidences of cardiovascular or pulmonary disease A detailed history of drug ingestion is helpful

To identify the abnormal pigment freshly drawn blood to which an anticoagulant has been added is centrifuged to determine if the pigment is extracellular or intracellular If the plasma is clear the whole blood may be shaken in air for 15 min If the blood remains dark intracellular pigments are present The blood should then be diluted 1 10 or 1 100 with water and examined in the hand spectroscope The absorption band of methemoglobin (630 mμ) may be confused with that of sulfhemoglobin (618 mμ) but on the addition of 2 or 3 drops of 5 per cent potassium cyanide the band due to methemoglobin disappears whereas the sulfhemoglobin band is unchanged The addition of hydrogen peroxide causes dissolution of the sulfhemoglobin band but not of the methemoglobin band

Treatment In patients with hereditary or congenital methemoglobinemia ascorbic acid a reducing agent may be given daily by mouth in an amount of 100 to 500 mg Methylene blue accelerates the normal cell reconversion mechanism and is effective in a daily dosage of 100 to 300 mg by mouth In patients with mild drug induced methemoglobinemia no therapy is necessary other than removal of the offending agent since reduction of the methemoglobin occurs rapidly as a result of the intact normal reconversion mechanism In those patients in whom therapy is necessary methylene blue 1 to 2 mg per kg body weight given intravenously over a 5 min period in a 1 per cent solution is the agent of choice If cyanosis has not disappeared within an hour a second dose of 2 mg per kg body weight should be given This drug may also be given orally in doses of 3 to 5 mg per kg body weight

SULFHEMOGLOBINEMIA

Sulfhemoglobin is a sulfur containing hemoglobin derivative The exact mode of linkage of the sulfur to the hemoglobin is unknown Sulfhemoglobin is not found in erythrocytes under normal circumstances Once it has been formed it is not reversible to hemoglobin the abnormal derivative *remaining in the erythrocytes until they are destroyed*

Sulfhemoglobinemia may result when one of the oxidizing drugs listed in Table 104 has been taken

Phenacetin (A P C Empirin Compound Anacin *Stanback) and acetanilid (Bromoseltzer) are* the drugs found most frequently to be the causative agents Constipation is present in at least half the patients and it has been suggested without documentary proof that this contributes to the development of the condition by enhancing the production of hydrogen sulfide in the bowel

Sulfhemoglobin is inert as an oxygen carrier and when it is present intense cyanosis results Somewhat less than 0 5 Gm sulfhemoglobin per 100 ml blood causes a degree of cyanosis equal to that of 1 5 Gm methemoglobin or 5 Gm reduced hemoglobin Although the concentration of sulfhemoglobin may be found to be as high as 10 Gm per 100 ml the life of the patient is not endangered and symptoms which can be attributed to the sulfhemoglobinemia are rarely present Since many of the patients in whom sulfhemoglobinemia develops are neurotic or are taking drugs for a chronic headache or constipation the symptoms which can be elicited are probably not attributable to the sulfhemoglobinemia Symptoms of bromide intoxication frequently complicate the clinical picture in those ingesting Bromoseltzer Once formed there is no way of removing the sulfhemoglobin except by phlebotomy In time the affected red corpuscles wear out and are destroyed Treatment requires interdiction of the offending drug and correction of the intestinal conditions causing the disorder

Enterogenous sulfhemoglobinemia is a term used to refer to the syndrome of sulfhemoglobinemia cyanosis and constipation or other evidence of disturbed bowel function without the history of the ingestion of an oxidizing or sulfur containing drug Rare cases of acquired hemolytic anemia with paroxysmal sulfhemoglobinemia and methemoglobinemia *have been reported*

kopenia suggests leukemia aplastic anemia disseminated lupus erythematosus or one of the splenic disorders

Treatment and Prognosis The first principles in the therapy of thrombocytopenic purpura are expectant management and a search for possible etiologic factors If one is found or suspected further exposure should be stopped Expectant therapy in addition to appropriate rest nursing and diet includes iron if there has been blood loss and blood transfusion if this loss has been severe The use of siliconized apparatus or plastic equipment in transfusion or the use of platelet rich bloods or both is helpful as a temporary measure but it is noteworthy that platelet transfusions have limited value since platelet survival tends to decrease progressively when repeated transfusions are given

These measures are recommended because spontaneous remissions are common especially in children They can be complete and permanent Remissions are particularly likely to occur if the onset has been acute and there is no history of previous hemorrhagic manifestations Unfortunately the danger of bleeding into a vital organ such as the brain makes the waiting period a trying one Recurrences are twice as common in females as in males A more or less chronic course punctuated perhaps by more acute phases is more often seen in adolescents and adults but occurs at all ages

The use of adrenocorticotropic hormone cortisone or prednisone is often associated with a decrease of bleeding phenomena and the thrombocytopenia may decrease or disappear but these effects are temporary These hormones are useful chiefly therefore in the management of hemorrhagic emergencies and in the preoperative preparation of patients for splenectomy Those which can be given orally are preferred In general 75 to 250 mg cortisone or 20 to 60 mg prednisone is given per day in divided doses

Splenectomy results in "cure" in approximately two-thirds of patients Following splenectomy the platelet count may increase rapidly and to abnormally high levels an effect which carries the danger of postoperative thrombosis or it may rise gradually Bleeding often ceases even though the platelet count may not have increased greatly an effect which suggests an influence of the spleen on capillary function In the bone marrow the previously abnormal megakaryocytes in most instances soon appear to be quite normal again and are seen to be surrounded by platelets Even when splenectomy is not followed by complete recovery considerable improvement can be expected It is of interest that remission following splenectomy is not necessarily accompanied by disappearance of the "thrombocytopenic factor"

Benefit is less likely to follow splenectomy in acute phases of bleeding than in the more chronic phases and the operative mortality is higher hence hasty resort to operation should be avoided and the patient should be prepared as described already

In these patients other operations should not be carried out before splenectomy has been done since the bleeding may be severe and serious

NONTHROMBOCYTOPENIC PURPURAS

There are a number of types of purpura which are not accompanied by thrombocytopenia In none of these disorders has an abnormality of the blood been recognized In all but one a very rare syndrome known as von Willebrand s disease bleeding time is also normal These purpuras have been discussed already (p 215) but allergic purpura and certain other rare purpuric disorders deserve more complete consideration

Allergic Purpura

In this form of purpura there is found one or more of the common symptoms of allergy such as erythema, urticaria or effusions of serum into subcutaneous or submucous tissues or viscera There may be concomitant articular symptoms (*Schonlein s purpura peliosis rheumatica*) crises of abdominal pain (*Henoch s purpura*) or no localized signs (*purpura simplex*) Constitutional symptoms such as fever and malaise may be present The manifestations may wax and wane in intensity extent and nature In various combinations erythema (multiforme bullosum, vesiculosum nodosum) urticaria and edema may be encountered Necrotic areas may develop to be followed by the formation of bullae or ulcers The skin lesions may appear in crops and may be accompanied by itching or paresthesias There may be hemorrhage from the visible mucous membranes Kidney lesions similar in nature to those found in the skin may develop and cause hematuria proteinuria, and profound though temporary disturbance of renal function

Etiology and Pathogenesis These purpuras are more common in children and young adults than in older age groups The true nature of these purpuras is unknown The resemblance to serum sickness suggests an allergic basis but only in a minority has an allergic cause been demonstrated In some cases the exciting agent appears to have been bacterial (streptococcus antityphoid vaccine) or an article of food (milk eggs pork strawberries etc) In others hypersensitivity to cold has appeared to be the factor Comparison of the sex ratio age of onset seasonal trends and incidence of previous upper respiratory tract infections particularly those associated with a hemolytic streptococcus and similarities in the latent period before

Table 105 CLASSIFICATION OF THROMBOCYTOPENIC PURPURAS

I Essential or primary purpura hemorrhagica idiopathic thrombocytopenic purpura (ITP)
II Symptomatic purpuras
  A Chemical vegetable animal and physical agents
    1 Chemical
      a Myelosuppressive agents nitrogen mustards TEM Myleran urethan antimetabolites benzol
      b Agents which in therapeutic doses produce purpura mainly because of individual sensitivity organic arsenicals Sedormid quinidine quinine sulfonamide gold salts and possibly other agents (oxytetracycline phenylbutazone Tridione dinitrophenol organic hair dyes estrogens DDT)
    2 Vegetable Foods orris root
    3 Animal Snake venoms pertussis vaccine insect bite
    4 Physical X rays and other forms of ionizing radiation heat stroke extensive burns
  B Blood disorders
    1 Leukemias Acute or late stages of chronic
    2 Anemias
      a Aplastic—idiopathic or due to physical or chemical agents
      b *Myelophthisic (tumors in bone marrow osteosclerosis etc)*
      c Pernicious anemia
      d Acquired hemolytic anemias of immune body type
    3 Splenic disorders Congestive splenomegaly Gaucher s disease Felty s syndrome rarely Hodgkin s disease
    4 Miscellaneous Acute purpura with platelet thrombi in capillaries (thrombotic thrombocytopenic purpura)
  C Infections and other conditions Septicemia subacute bacterial endocarditis typhus measles vaccinia infectious mononucleosis etc lupus erythematosus sarcoidosis hemangioendothelioma massive blood transfusions

SOURCE Adapted from M M Wintrobe Clinical Hematology 4th ed Philadelphia Lea & Febiger 1956

in that they do not blanch on pressure Often ecchymoses are found as well Mucous membrane hemorrhages are common bleeding from the nose mouth or uterus being particularly frequent and sometimes severe Not rare are instances in which menorrhagia is the chief complaint and this often is the only prominent clinical sign other than the abnormalities in the blood Bleeding however may occur into any tissue and from any orifice Frequently also excessive bleeding may be noted following tooth extraction tonsillectomy operations or injuries

Fever of mild degree may be present in acute cases *The spleen may extend a fingerbreadth below* the costal margin There is no general glandular enlargement sternal tenderness or other physical sign other than those attributable to hemorrhage or anemia

Blood and Bone Marrow Findings These have in the main been mentioned already What platelets may be seen in the blood smear are often unusual in appearance giant or minute forms or deeply stained ones The bleeding time may be slightly moderately or greatly prolonged (8 to 60 min or *more)* Anemia *if present* is proportional to the amount of blood lost If there has been much bleeding signs of stimulated erythropoiesis will be found reticulocytosis polychromatophilia even occasional normoblasts The leukocyte count may be normal but if acute blood loss has taken place there may be a moderate leukocytosis with slight shift to the left In some chronic cases lymphocytosis has been observed

Diagnosis Hemorrhage not due to obvious cause if associated with thrombocytopenia prolonged bleeding time poor clot retraction and positive tourniquet test can be attributed to thrombocytopenic purpura Prolonged bleeding time is characteristic of von Willebrand s disease (p 1204) and may be found though rarely in a number of conditions in which coagulation time is prolonged provided the blood and tissues are severely impoverished in coagulation factors (see Table 20 *Chap 23 p 221) These include hemophilia and* hypoprothrombinemia A positive tourniquet test is found in many circumstances other than thrombocytopenic purpura (p 221) Poor retraction of the clot is found with rare exceptions only when the platelets are reduced in number The combination of these abnormalities is characteristic of thrombocytopenic purpura

Before a diagnosis of purpura hemorrhagica can be made however the recognized causes of thrombocytopenic purpura must be excluded They are listed in Table 105 The history and physical examination will serve to rule out many of these conditions Adenopathy and sternal tenderness as well as anemia out of proportion to the blood loss even in the absence of striking changes in the leukocytes should suggest leukemia Persistent leu

the clotting defect is similar to that in true hemophilia but which cannot be so regarded for various reasons

216 HEMOPHILIA AND RELATED DISORDERS

M M Wintrobe

HEMOPHILIA

Definition Hemophilia is a constitutional anomaly of blood coagulation which depends on the inheritance of a sex linked recessive mendelian trait transmitted by the female and affecting only males It is characterized by a lifelong tendency to excessive bleeding The coagulation time is prolonged

History Although a clear description of this disorder was not published until 1803 by Otto of Philadelphia it is apparent from passages in the Talmud that the condition was known to the ancient Jews who even proscribed circumcision in those whose family history suggested this disorder

Etiology and Pathogenesis The factor or gene responsible for the development of hemophilia appears to be carried in the X chromosome of the reproductive cells The disease is limited to the male and is transmitted from the male through an unaffected daughter to a grandson The daughters of an affected male transmit the trait as an evident defect to half their sons and as a hidden (recessive) characteristic to half their daughters The occurrence of hemophilia in the female would require the marriage of a hemophiliac male with a carrier female Such cases have been described but they are exceedingly rare Sporadic cases of hemophilia have been described in which the family history was negative These can sometimes be explained by long inheritance through females with the males being by chance unaffected Illegitimacy may be responsible for other instances while still others may represent the disease arising *de novo*

It has now been shown that the abnormality in hemophilia is due to the absence or reduction in the blood of a component essential for the formation of plasma thromboplastin ("thromboplastinogen" antihemophilic globulin) The role which this substance plays in the process of coagulation was discussed earlier (Chap 23)

Symptomatology Hemorrhage usually following trauma but sometimes spontaneous is the essential symptom The bleeding is in the nature of a persistent slow oozing which is out of all proportion to the extent of the injury This tendency to prolonged bleeding usually appears in early childhood even in infancy The bleeding may last not only hours but days and even weeks and may lead to profound anemia Subcutaneous and intramuscular hemorrhages are common Petechiae are very rare Hematomas may be large There may be severe bleeding from the mouth gums lips tongue or gastrointestinal tract Epistaxis is a common symptom The eruption and loss of teeth may be accompanied by severe bleeding Hematuria is relatively common and hemorrhage into joints is characteristic Recurrences are the rule and ultimately a permanently swollen joint with local deformity contractures and muscular atrophy is produced

The *blood* in typical cases is normal except for the prolonged coagulation time and the manifestations which hemorrhage produces (p 1171) Cur

the onset of symptoms suggest a close relationship between the Henoch Schonlein syndrome and acute nephritis

It is likely that an antigen antibody reaction occurs which takes place especially in the endothelium of certain blood vessels As a result there is an alteration in the permeability of the small blood vessels Perivascular inflammation has been observed about the small vessels of the corium of the skin The various manifestations arise from extravasations of varying proportions of plasma and formed elements of the blood Mechanical factors may possibly influence the localization of the lesions in addition to the local vascular changes In Henoch s purpura an urticarial serohemorrhagic effusion into the intestinal wall is the cause of the colicky pain and sometimes even leads to intussusception

Diagnosis Diagnosis is most difficult when purpura is not present or not obvious In Henoch s purpura crises of pain may develop which in the absence of purpura and accompanied as they may be by leukocytosis cannot be clearly distinguished from acute abdominal conditions which call for operative intervention Eosinophilia may be present and then an allergic rather than an inflammatory reaction may be suspected Acute nephritis may be simulated when the kidney is involved Hematuria may be a prominent symptom in such cases just as melena may occur in Henoch s purpura The Schonlein type may be mistaken for rheumatic fever

When purpura is discovered and there are exudative skin lesions at the same time diagnosis is much easier since these lesions are not encountered in other forms of purpura as a rule Various chemical agents (e g quinine) may also produce non thrombocytopenic purpura Furthermore this may be a symptom of a variety of diseases already discussed (p 215)

Treatment and Prognosis Treatment is purely symptomatic Naturally if an etiologic agent is discovered or suspected further exposure should be eliminated Desensitization may be attempted if the exciting agent is protein in nature Allergic purpura is rarely fatal Individual attacks last from 1 to 6 weeks Recurrences at intervals of months or years are not unusual however and in some cases glomerulonephritis has developed in association with or in the wake of the purpuric disorder with the consequences usual in that condition Hormone therapy (ACTH cortisone) has been found to produce symptomatic benefit

Other Hemorrhagic (Purpuric) Disorders

A variety of hemorrhagic disorders characterized in the main by spontaneous bleeding from the mucous membranes and from the internal surfaces of the body and often by petechiae and ecchymoses as well have been described which cannot be fitted into the categories already discussed Posttraumatic and postoperative bleeding is not unusual in these cases Of these conditions *one von Willebrand s* disease is becoming better defined as an entity another Glanzmann s thrombasthenia is less clearly delineated

Von Willebrand's disease a hemorrhagic diathesis inherited as a simple mendelian dominant and affecting both sexes is characterized by prolonged bleeding time normal platelet count normal coagulation time and normal clot retraction The tourniquet test may or may not be positive The tendency to bleed appears early in childhood and takes the form of epistaxis bleeding from the gums or from the female genitalia Hemorrhage from the gastrointestinal or urinary tract may occur and there may be prolonged bleeding from injuries and operation sites The underlying defect in von Willebrand s disease may be an inherited abnormality of the capillaries of the skin and mucous membranes They have been described as distorted and often bizarre in form and fail to contract after injury

Under the title of *vascular hemophilia* several families have been described in which the characteristic features of von Willebrand s disease were associated with deficiency of antihemophilic globulin Inheritance of this disorder appears to be that of a non sex linked autosomal dominant with high penetrance and variable expressivity

Glanzmann s thrombasthenia is a term which has been applied to cases of excessive hemorrhage in which the bleeding time platelet count and coagulation time were normal but clot retraction was deficient and the platelet morphology abnormal This is the foundation of the concept of *thrombocytopathic purpura* in which it is assumed that bleeding occurs because of a *qualitative* rather than a quantitative platelet defect It is possible that several varieties of thrombocytopathic purpura depending on disturbances in any one of the several platelet functions may become better defined in time Thus in the so called *Glanzmann Naegeli* type of thrombasthenia small round platelets have been described normal or increased in number but with impaired adhesiveness and agglutinability Although clot retraction is poor prothrombin consumption is normal and coagulation time is normal

Surgical procedures in cases such as these should be avoided Bleeding is managed by pressure the application of thrombin fibrin foam and blood transfusion when necessary

The term *pseudohemophilia* which von Willebrand applied to the condition he described is unsatisfactory and if it must be used at all is more *appropriately applied to cases of abnormal bleeding* associated with prolonged coagulation time in which

ing proportions to normal blood The clotting of normal blood is not delayed by the addition of even 50 per cent of hemophilic blood

The one stage prothrombin time separates hemophilia from conditions associated with true prothrombin factor V and factor VII deficiencies and also from many cases in which there is a circulating anticoagulant In hemophilia in contrast to these conditions prothrombin time is normal The deficiency in hemophilic blood can be corrected by the addition of a small proportion of normal plasma The degree of reduction in antihemophilic globulin content can be assayed roughly by this means

It was pointed out earlier that assays for antihemophilic globulin have revealed a *mild* form of *hemophilia* in which even prothrombin consumption is normal or equivocal An additional observation of interest is the fact that unlike classic hemophilia some of the heterozygotes show a diminution in antihemophilic globulin a finding which suggests that the gene is not completely recessive as it is in classical hemophilia and for this reason the condition has been attributed to an allelic mutant of the hemophilia gene In female carriers of classic hemophilia no evidences of a coagulation defect have been demonstrated thus far and no deficiency of antihemophilic globulin has been found

Another entity clinically indistinguishable from classic hemophilia is referred to as *plasma thromboplastin component (PTC) deficiency* and *Christmas disease* The condition is due to the lack or deficiency of a coagulation factor necessary for the formation of thromboplastin which is present in normal and in hemophilic plasma Both severe and mild forms of the disorder have been encountered The coagulation time is usually prolonged and prothrombin consumption is impaired but cases with normal values have also been observed The missing coagulation factor is most readily obtained from serum Since this condition resembles hemophilia in its clinical manifestations and mode of inheritance it has been called *hemophilia B* the letter *A* being used to refer to the classic condition The two types of hemophilia can be distinguished in vitro by the correction of the coagulation defect of the one by the other and of both by the addition of normal plasma Another simple test consists in the correction of the clotting defect in PTC deficiency by the addition of normal serum and the failure of such correction in classical hemophilia

Still other disorders resembling hemophilia have been described They include *plasma thromboplastin antecedent (PTA) deficiency* which differs from hemophilia and PTC deficiency in that the manifestations occur in *either sex* The condition appears to be transmitted as an autosomal dominant trait with a high degree of penetrance but variable expression Spontaneous bleeding is rare bleeding has occurred usually following trauma or a surgical procedure including tooth extraction Various degrees of severity have been observed ranging from a severe form with prolonged coagulation time and markedly abnormal prothrombin consumption, to a mild form with normal coagulation time and only slightly impaired prothrombin consumption Thromboplastin generation is markedly impaired The deficiency in this disorder is corrected both by plasma absorbed with $BaSO_4$ which corrects AHG deficiency and by serum which corrects PTC deficiency PTA is a globulin which is stable on storage and is present in normal serum where it is localized in the β_2 globulin fraction Studies of the relative incidence of hemophilia PTC and PTA deficiencies have yielded ratios of approximately 15 2 1

A possible *fourth plasma thromboplastin component* (PTF D) has been described as the deficiency underlying the occurrence of frequent and severe epistaxes and imperfect hemostasis after tooth extraction or serious trauma In the reported cases coagulation time was prolonged prothrombin consumption was reduced and thromboplastin generation retarded The deficient factor has been characterized as heat labile and storage stable and as being present in both normal plasma and serum The blood of patients with PTA and that of patients with "fourth component deficiency have been found to be mutually corrective

Some investigators doubt the existence of the fourth component while some have reported cases in which still other factors (e g Hageman factor) were thought to be deficient

Course and Prognosis The tendency to bleed varies from time to time and differs in degree from one family to another The typical hemophiliac patient rarely survives to adulthood without suffering some disabling deformity of the joints The prognosis differs however in accordance with the severity of the AHG deficiency Death may occur from exsanguination following surgical procedures or accidental cuts Less often it is due to internal hemorrhage

Treatment The prevention of hemophilia depends on appropriate restriction of marriage or at least of propagation Only unaffected males can marry with any assurance that the hemorrhagic tendency will not be transmitted

Affected individual and male children of tainted stock must be guarded against trauma and surgical measures even the most minor ones should be avoided whenever possible If some procedure which may entail bleeding is absolutely necessary

Table 106 BLEEDING AND COAGULATION TESTS IN VARIOUS HEMORRHAGIC DISORDERS

Disease or condition	Thrombocytopenia	Bleeding time prolonged	Clot retraction poor	Tourniquet test positive	Coagulation time prolonged	Prothrombin time (one-stage) prolonged	Prothrombin consumption impaired
Purpura thrombocytopenic	+	+	+	+	−	−	+
Purpura nonthrombocytopenic	−	−	−	±	−	−	−
Hemophilia (hemophilia A)	−	−*	−	−	+†	−	+†
PTC deficiency (hemophilia B)	−	−	−	−	+†	−	+†
Dicoumarin excess	−	−	−	−*	−*	+	−
Factor V deficiency	−	−	−	−	+†	+	+
Factor VII deficiency	−	−	−	−	+†	+	−
Hypoprothrombinemia	−	−	−	−	+	+	−
Afibrinogenemia	−	+†	−	−	+	+	−
Anticoagulant excess	−	−*	−	−	+	±	±
von Willebrand's disease	−	+	−	±	−	−	−

* May be prolonged if condition is severe
† May be normal if condition is mild

ously the degree of prolongation of coagulation time like the symptoms of this disorder varies from time to time Platelets are normal in number Only *rarely is bleeding time prolonged*

It has been shown that cases of hemophilia occur which are less severe than the classic type just described Assays of plasma antihemophilic globulin (AHG) have shown a great range in the quantity of this essential substance Four grades of hemophilia have been distinguished viz classical hemophilia in which the plasma AHG is 0 per cent moderate hemophilia characterized by the occurrence of subcutaneous hematomas and post operative hemorrhages essentially normal coagulation time normal prothrombin consumption and less than 3 per cent AHG mild hemophilia in which coagulation time and prothrombin consumption are normal and the plasma AHG is approximately 16 per cent and subhemophilia in which there may only be a history of prolonged postoperative oozing The plasma AHG is in the neighborhood of 33 per cent as compared with the normal value of 65 to 136 per cent Frequently the severity of the disorder is constant in a given family as if not only the defect but also its degree were an inherited characteristic

The *bone marrow* is normal except for normoblastic hyperplasia when hemorrhage has been severe

Diagnosis Although hemophilia and purpura hemorrhagica are often confused with each other differentiation is easy as a rule for the latter condition involves thrombocytopenia prolonged bleeding time poor clot retraction and a positive tourniquet test In hemophilia the patient is normal in *these respects and in the classical disorder coagulation time is prolonged* There is in addition the history of repeated protracted hemorrhage usually first manifested in early childhood as well as the characteristic family history Occasionally difficulty in diagnosis may arise if attention is attracted only to the joint manifestations or to a swelling not recognized as a hematoma In a similar manner the bleeding may suggest kidney disease pulmonary disease or peptic ulcer

Other Disorders of Coagulation The development of more precise methods of laboratory examination has resulted in the discovery of new entities hitherto confused with classic hemophilia and the purpuras in addition to recognition of the fact that mild forms of hemophilia exist Many of these disorders were mentioned earlier (Chap 23) The results of various laboratory tests in a number of these conditions are presented in Table 106

In cases of hemophilia with normal or only slightly impaired coagulation time the prothrombin *consumption test will be found reliable and* sensitive although it is not specific reduced prothrombin consumption is found also in various disorders associated with thrombocytopenia as well as in patients with hemorrhagic manifestations due to anticoagulants affecting thromboplastic activity The absence of a circulating anticoagulant can be demonstrated by adding the patient s blood in vary

217 AGRANULOCYTOSIS AND THE PANCYTOPENIAS

M M Wintrobe

AGRANULOCYTOSIS

Definition Agranulocytosis (agranulocytic angina) is a disorder characterized by severe sore throat marked prostration and extreme reduction or even complete disappearance of the granulocytes from the blood This clinical picture first recognized by Schultz in 1922 was observed most frequently in women of middle age and often ended in sepsis and death An etiologic relationship to the taking of certain drugs has been demonstrated

Etiology and Pathogenesis In 1931 Kracke pointed out that the sudden appearance of this syndrome corresponded with the introduction of certain coal tar derivatives as therapeutic agents This was borne out by considerable circumstantial evidence which incriminated in particular the antipyretic aminopyrine (Pyramidon) The course of events in affected individuals would seem to be (1) granulocytopenia as the result of some effect induced by the drug (2) loss of resistance to infection development of sore throat (3) overwhelming sepsis and death That some form of tissue injury in addition to leukopenia may be a factor in the pathogenesis of this syndrome is suggested by the frequency with which one may encounter leukopenia even of severe degree following nitrogen mustard therapy without sepsis developing

The most striking change observed in the bone marrow is a lack of juvenile and segmented neutrophilic leukocytes less mature forms being plentiful This picture has been referred to as maturation arrest but it could as readily result from abnormal peripheral destruction of the leukocytes or their segregation somewhere

Drugs producing leukopenia may be divided into two main groups—namely those which produce this effect in all individuals if given in sufficient amounts and those which cause leukopenia only in certain sensitive persons (Table 107) Various data suggest that between 0 5 and 4 per cent of patients taking the second group of drugs develop granulocytopenia In group III are listed drugs which have been incriminated in a few case reports but they cannot be regarded as well established causes of leukopenia

It is likely that granulocytopenia develops by more than one mechanism Some cases are encountered in which no drug seems to be incriminated Those drugs which produce granulocytopenia in all persons when given in sufficient amounts probably do so through their toxic effects Agents such as aminopyrine probably require a peculiar sensitivity or idiosyncrasy on the part of the patient

Table 107 LEUKOPENIA PRODUCING DRUGS

Group I—regularly produce leukopenia if given in sufficient amounts
- Benzene
- Mustards (sulfur and nitrogen mustards TEM etc)
- Urethan Myleran Demecolcin
- Antimetabolites (antifolic acid compound 6-mercaptopurine etc)

Group II—produce leukopenia in "sensitive" persons only
- Analgesics (aminopyrine phenylbutazone etc)
- Antithyroid drugs (thiouracil methimazole etc)
- Anticonvulsants (trimethadione phethenylate etc)
- Sulfonamides [sulfanilamide sulfisoxazole (Gantrisin)]
- Antihistamines (Pyribenzamine phenothiazine etc)
- Antimicrobial agents (organic arsenical chloramphenicol)
- Miscellaneous (dinitrophenol chlorpromazine gold salts etc)

Group III—very rarely cause leukopenia if at all
- Barbiturates (acetanilid acetophenetidin)
- Quinine
- Cinchophen etc

Rarely other manifestations of sensitivity such as rash urticaria and edema may be present or may have occurred on other occasions Furthermore in patients who have recovered from aminopyrine induced agranulocytosis the administration of small amounts (0 2 Gm) of the drug may be followed within 6 to 10 hr by disappearance of all the neutrophils from the blood It has also been shown that the blood of such a person withdrawn 3 hr following ingestion of the drug produces outspoken granulocytopenia within 20 to 40 min after its transfusion into normal persons In the plasma and serum of the sensitive patient a substance has been found at the height of the aminopyrine granulocytopenia which produces agglutination of homologous and heterologous leukocytes If as seems likely an immune mechanism is involved in the pathogenesis of this type of granulocytopenia removal of the agglutinated leukocytes from the circulating blood may be postulated with resulting depletion of the more mature forms from the bone marrow

Symptomatology The condition described by Schultz was an *acute fulminating disorder* In such cases there may be a prodromal period marked only by malaise or moderate fever which often is overlooked If the granulocytopenia is recognized at this stage and sepsis is prevented or does not develop no other manifestations may appear If infection supervenes or if the condition is first recognized at this stage the onset appears to be sudden and is marked by a chill high fever and often sore throat *Prostration is extreme* Gangrenous ulceration may be found on the gums tonsils soft palate lips pharynx or buccal mucous membranes Regional

it should be done only in a hospital and when plentiful amounts of fresh blood and plasma or antihemophilic globulin are available Normal plasma kept solid or dried lyophilically within a few hours of its withdrawal from the body will retain its antihemophilic effect almost indefinitely Although as little as 50 ml fresh plasma will maintain the coagulation time of a hemophiliac of moderate severity within normal limits for about 24 hr in practice it is wise to use much larger amounts When internal bleeding occurs transfusions of blood and plasma are the only measures of value and carry the minimum of risk Surgery is contraindicated Prior to any surgical measure such as tooth extraction at least 500 ml fresh plasma should be given In contrast to its effectiveness in PTC deficiency serum is devoid of activity in classic hemophilia

An essential in the local management of bleeding in hemophilia is the avoidance of tissue injury The existence of damaged or devitalized tissue merely prolongs the period of subsequent hemorrhage Thus for example in dental extraction gum margins should not be sewn together When there is free bleeding pressure must naturally be applied but it should be temporary and gentle and should be supplemented by the use of coagulants such as Russell's viper venom or thrombin ("hemostatic globulin") These measures may be followed by the application of absorbable hemostatic dressings such as human fibrin fibrin foam gelatin sponge or oxidized cellulose Following tooth extraction a previously made dental splint will keep the dressing in place with a minimum of movement

Unfortunately in some patients with hemophilia antibodies with an anticoagulant action have developed following transfusion or treatment with antihemophilic globulin This appears to be due to immunization against the latter substance

HEREDITARY HEMORRHAGIC TELANGIECTASIA

Definition This is a vascular anomaly characterized by multiple dilatations of capillaries and venules in the skin and mucous membranes The anomaly is transmitted as a simple dominant by both sexes

Etiology The telangiectases may be found in childhood but they increase in number as age advances Bleeding may not commence until adult life has been reached

Symptomatology Epistaxis is especially common but bleeding may come from telangiectases wherever they are the face tongue lips or gastrointestinal respiratory or genitourinary tracts Those on the skin are less likely to bleed than are telangiectases on mucous membranes The telangiectases range from pin point to about 3 mm in diameter are bright red or violaceous in color and characteristically blanch on pressure Sometimes they form nodular vascular tumors the size of a split pea such lesions resemble those of a very rare probably nonhereditary condition angiokeratoma corporis diffusum (Fabry) In elderly patients some of the lesions may become spiderlike resembling those associated with hepatic insufficiency Trivial trauma sustained by these abnormal relatively exposed vessels results in an unusual amount of bleeding The blood is normal except for the effects hemorrhage may have produced The tourniquet test is negative

Diagnosis This depends on recognition of the vascular anomalies which are easily overlooked Purpuric spots do not fade on pressure

In a number of cases of this disorder pulmonary arteriovenous fistula has been observed

Treatment The telangiectatic vessels are excessively fragile but oxidized cellulose (Oxycel) Gelfoam or similar hemostatic agents usually suffice to control an existing hemorrhage if they are applied carefully Although the primary bleeding site can be cauterized or destroyed by electrocoagulation satellite lesions soon form nearby Prophylaxis is unsatisfactory Many procedures have been tried including estrogen and androgen therapy with doubtful effect

size and not at all in shape Bleeding time is usually moderately prolonged the clot retracts poorly and the tourniquet test is positive Coagulation time is normal

The onset of the disorder is insidious The symptoms may be those attributable to anemia or the effects of thrombocytopenia or of granulocytopenia may dominate the clinical picture There is striking often "waxy" pallor but weight loss is unusual There may be bleeding from the nose mouth vagina or elsewhere Hemorrhages may be found in the eye ground or skin Ulceration in the mouth and pharynx or other evidence of infection may be encountered There is no sternal tenderness splenomegaly or hepatomegaly and lymph node enlargement if present is found only in relation to local infection

This picture may follow exposure to a variety of *chemical and physical agents* As with the causes of granulocytopenia the agents associated with the occurrence of aplastic anemia may be divided into two groups viz (1) those which regularly produce marrow hypoplasia and aplasia if a sufficient dose is given and (2) those which are only occasionally associated with such a change and presumably depend on idiosyncrasy In the former category may be included ionizing radiation (roentgen rays radioactive phosphorus etc) the mustards (sulfur and nitrogen mustards TEM etc) urethan Myleran benzol and the antimetabolites (antifolic acid compounds 6 mercaptopurine etc) It will be noted that these agents have been or are used in the treatment of leukemia Hodgkin s disease and related disorders Excessive dosage will result in the production of marrow aplasia Benzene (benzol) is no longer used in the treatment of leukemia but it is employed in many industries (leather enamel rubber lacquer electroplating airplanes linoleum celluloid etc) and must thus be kept in mind when aplastic anemia is encountered in a person working in one of these industries Of the agents occasionally associated with the occurrence of hypoplasia or aplasia of the bone marrow the following should be mentioned in particular antimicrobial agents (arsenobenzols chloramphenicol) anticonvulsants (Mesantoin) antithyroid drugs antihistamines insecticides and various miscellaneous agents such as gold preparations and trinitrotoluene Although the evidence incriminating these drugs is only circumstantial a sufficient number of cases has been reported to make it seem very likely that development of aplastic anemia following exposure to the drugs named is more than a coincidence Less convincing is the evidence that other drugs are the cause of aplastic anemia since there are only single or very few reports incriminating them In this last group may be mentioned the sulfonamides oxytetracycline chlortetracycline Tridione Nuvarone Carbimazole Tapazole quinacrine phenylbutazone chlorpromazine and various hair dyes and volatile insecticides

"*Idiopathic* cases have also been described in which exposure to an offending agent could not be discovered Such cases have been observed most frequently in young adults or adolescents Still another form of pancytopenia with hypoplastic bone marrow has been observed usually at an even younger age which may be familial and is associated with a variety of congenital defects (bone abnormalities particularly of the forearms and thumbs microcephaly hypogenitalia genitourinary tract abnormalities) and a generalized olive brown pigmentation of the skin (*Fanconi syndrome*)

In addition to such cases of classic aplastic anemia a very similar clinical and hematologic picture can be observed in the face of a bone marrow picture which is cellular or even hyperplastic In still other cases little or no reduction was present in the leukocyte or platelet count Such *pure erythrocyte hypoplasia* has been observed as a congenital disorder but rarely it appears also to be acquired In some of these cases occasional nucleated red corpuscles polychromatophilia stippling and immature white cells have been found in the blood and splenic and hepatic enlargement and even general lymphadenopathy have been described Whether all these cases should be classed with the true aplastic anemias under one category of re fractory anemias" is a question which cannot be settled until their pathogenesis is clear That these various pictures may be variants of the same fundamental process is suggested by the observation that benzene poisoning not only may produce aplastic anemia but also can be associated with a regenerative blood picture including even a leukemoid reaction and the bone marrow may be hyperplastic rather than acellular Again *internal irradiation* produced by the ingestion of radium by watch dial workers was found to be characterized by *macrocytic* anemia with nucleated red corpuscles in the blood and bone marrow with primitive red corpuscle and leukocyte hyperplasia

Myelophthisic Anemia

This term is applied to the type of anemia associated with space occupying disorders of the bone marrow Metastatic carcinoma (for example that arising from malignancy of the breast prostate lung kidney adrenal or thyroid) leukemia multiple myeloma and a rare disorder known as *myelofibrosis* or myelosclerosis are conditions which produce *myelophthisic anemia* In *myelosclerosis* there is an irregular increase of fibrous or bony tissue in the bone marrow which is often associated with progressive anemia The outstanding symptom is splenomegaly The course is very slow Bone

adenopathy may be present but generalized adenopathy and sternal tenderness are not found and splenomegaly when present is minimal Brawny edema of the neck can become extreme Necrosis of the gastrointestinal tract may occur Jaundice has been described in some cases In fatal cases the duration of the illness is 3 to 9 days

In the blood granulocytopenia is the outstanding finding Since the leukocyte count is usually under 3 000 per cubic millimeter and often is as low as 500 a reduction in the absolute number of all cells actually takes place Of the leukocytes which remain 95 to 100 per cent may be lymphocytes Anemia and thrombocytopenia are not found If present another cause should be suspected

The *bone marrow* is normal except for the "maturation arrest described already

In addition to the acute form described above *chronic cyclic* and *recurrent* forms of granulocytopenia have been observed They may or may not be related to the acute disorder In the chronic cases the course is prolonged and infections which often are relatively resistant to therapy especially in the skin and oral cavity occur repeatedly Hypo*plasia of granulocytic precursors in the bone mar*row slight splenomegaly and absolute lymphocytosis and monocytosis have been described In other instances there is a cyclic or recurrent periodicity of attacks at intervals of weeks or months with more or less normal leukocyte counts in the symptom free period Unexplained fatigue is a common complaint In some cases the leukopenia has been observed to occur in remarkably regular 3 week cycles (*periodic neutropenia*)

Primary splenic neutropenia is a name applied to a clinical picture characterized by fever pain over the splenic region and splenic enlargement granulocytopenia and essentially normal or somewhat hyperplastic bone marrow The manifestations may be acute subacute or chronic and have been attributed to excessive lysis of neutrophils by the spleen Splenectomy is reported as bringing complete relief and excessive phagocytosis of leukocytes can then be demonstrated in that organ The disorder is very rare

Diagnosis The clinical picture may suggest a variety of buccal and pharyngeal infections The great majority of these infections however are accompanied by leukocytosis Infections characteristically accompanied by leukopenia such as measles undulant fever and typhoid should rarely give difficulty although influenza may Aleukemic leukemia may present a similar clinical picture but the presence of sternal tenderness general glandular enlargement and splenomegaly as well as anemia thrombocytopenia and usually very immature leukocyte in the blood makes differentiation no serious problem Aplastic anemia is recognized by evidence of involvement of red corpuscles and platelets as well as leukocytes

Treatment and Prognosis The offending drug must be searched for and its further use prohibited Of equal importance is the administration of chemotherapeutic agents such as penicillin which will hold the infection in abeyance until leukocyte formation becomes normal and is able to cope with the offending organisms There is no conclusive evidence that various agents which have been proposed as stimulants of leukocyte recovery including one which was at one time very popular Pent nucleotide are of any value Before the sulfonamides and penicillin were available the prognosis was very poor Mortality was as high as 70 to 90 per cent With modern chemotherapy only a small proportion of patients fail to recover During recovery with the reappearance of leukocytes abscesses may develop which will require appropriate therapy

Splenectomy has been associated with considerable improvement or even recovery in some cases of the recurrent and cyclic variety but this result is unpredictable The steroid hormones may be of temporary value perhaps in the cases most likely to respond to splenectomy In the chronic cases with hypoplastic bone marrow splenectomy has not been found to be helpful

THE PANCYTOPENIAS

Definition The term *pancytopenia* refers to a reduction in the number of all three formed elements of the blood the red corpuscles the leukocytes and the platelets This is not a disease entity but a triad which is encountered under a widely differing group of circumstances

Classification This triad may be encountered in aplastic or hypoplastic" anemia in "aleukemic or subleukemic leukemia in myelosclerosis and other myelophthisic anemias in pernicious anemia and in association with a number of disorders of the spleen Under this heading agnogenic myeloid metaplasia and primary splenic panhematopenia must also be considered

Aplastic Anemia

This term in its strict sense refers to a condition in which signs of hematopoiesis are lacking in the bone marrow fat having replaced the blood forming tissue At the same time there are anemia granulocytopenia and thrombocytopenia There are no signs of blood regeneration The reticulocyte count is very low or zero there is no polychromatophilia or basophilic stippling and nucleated red corpuscles and immature leukocytes of all types are absent The anemia is usually normocytic sometimes macrocytic the red corpuscles vary little in

218 THE LEUKEMIAS
M M Wintrobe

Definition Leukemia is a disease probably of neoplastic nature which is characterized by widespread and abnormal proliferation of the leukocytes and their precursors throughout the body and particularly in the bone marrow spleen and lymph nodes There are different types of leukemia differentiated mainly according to the predominant abnormal cell forms The morbidity of the process ranges from a very acute disorder of but a few weeks duration to a very chronic one compatible with life even for many years The termination however is always fatal

History Knowledge of leukemia can be traced back to the period from 1839 to 1845 when Donne made the first microscopic observations and Craigie Bennett and Virchow distinguished the clinical entity Virchow recognized the cells as being leukocytes not pus cells and distinguished a lymphatic and a splenic type of leukemia With the development of Ehrlich s blood staining methods in 1891 Neumann s myelogenous form was recognized as being the same as Virchow s splenomegalic type Acute leukemia was recognized by von Friedreich in 1857 and by Ebstein in 1889 and the myeloblastic form was separated from the lymphoblastic type when Naegeli described the myeloblast in 1900 Reschad and Schilling Torgau described monocytic leukemia in 1913 Since then variations from the classic pictures have been recognized and method for palliative management have been developed but little advance has been made in gaining an understanding of the actual cause of this invariably fatal process or in its prevention or specific treatment

Varieties of Leukemia and Incidence of Various Types Acute and chronic forms of leukemia can be distinguished on clinical grounds as well as on the basis of the predominant abnormal cell types Without treatment acute leukemia usually is fatal within 6 *months* the duration of life in chronic leukemia may be several usually 3 to 5 sometimes 1 or 2 and in other cases 10 or more *years* "Subacute" leukemia is not truly intermediate between acute and chronic leukemia The course and the clinical and hematologic pictures resemble those of the acute form but the progress of the disease is slower than in the acute form of the disease Since myeloblasts lymphoblasts myelocytes lymphocytes or monocytes are the predominant cells in the great majority of cases of leukemia the terms *acute* or *chronic* (and if one wishes *subacute*) qualified by the name of the predominant cell type appear to be the most satisfactory designations for the different varieties of leukemia

Leukocytosis is found in the majority of cases of leukemia "Aleukemic or more correctly subleukemic leukemia refers to cases in which leukocytosis is absent Such cases are more often acute than chronic

Leukemia is as common a cause of death as diphtheria or measles Deaths from leukemia represent about 3 6 per cent of those due to cancer There has been a steady increase in the number of deaths from leukemia the number having tripled since 1930 Contrary to earlier statistics it appears now that the proportions of cases of chronic myelocytic and chronic lymphocytic leukemia are approximately equal Chronic leukemia is perhaps twice as common as the acute variety The incidence of the various types of acute leukemia including monocytic leukemia is difficult to determine because conclusions must be based on differences in interpretation In various series 11 to 21 per cent of the cases were subleukemic

Etiology and Pathogenesis While any variety of leukemia may occur at any *age* it is nevertheless true that acute leukemia is much more common before the age of twenty five than later and is especially frequent under five years of age chronic myelocytic leukemia has its highest incidence between the ages of twenty five and forty five and chronic lymphocytic leukemia is seen especially after the age of forty five or fifty A difference in the sex incidence of leukemia becomes perceptible as age advances there being essentially no difference in the occurrence of acute leukemia in male and female children and young adults a slight preponderance of chronic myelocytic leukemia in males and a distinct preponderance of chronic lymphocytic leukemia in males (3 1)

On the basis of past experience it can be stated that the probability that leukemia will occur *more*

marrow involvement may also occur in Hodgkin s disease and in the primary xanthomatoses (Gaucher s disease Niemann Pick disease Schuller Christian disease)

Agnogenic Myeloid Metaplasia

The term agnogenic myeloid metaplasia has been applied to cases in which the spleen showed marked myeloid metaplasia apparently as the result of a compensatory reaction This does not seem to be a disease entity The bone marrow has been variously fibrotic hyperplastic aplastic or normal The blood picture has varied like that described under Myelophthisic Anemia above In some cases jaundice was present In a number of instances a history of exposure to certain industrial solvents including benzene and carbon tetrachloride was obtained

Primary Splenic Panhematopenia

Primary splenic panhematopenia is the term which has been applied to cases associated with splenomegaly in which all three formed elements of the blood have been reduced in number and where excessive phagocytosis of these elements by the splenic macrophages has been conceived as being the fundamental disorder Splenectomy is described as producing dramatic improvement In these cases little or no evidence of increased blood destruction has been observed the reticulocyte percentage has been slightly or greatly increased polychromatophilia has been noted and the bone marrow picture has been one of hyperplasia As will be pointed out in the next section many splenic disorders are accompanied by pancytopenia

Diagnosis and Treatment It is evident from this outline that pancytopenia may be due to a number of causes of greatly varying nature The recognition of the underlying disorder will depend on thorough study which includes a painstaking history with careful inquiry about possible exposure to toxic agents thorough physical examination and bone *marrow examination in addition to a complete* survey of the blood

While the *blood picture* in these conditions may be that of a pancytopenia it is necessary to stress that *this is not* always the case Anemia is variable in degree It may be normocytic or macrocytic and nucleated red corpuscles may be seen in the blood even when there is little anemia Reticulocytes may be increased and polychromatophilia and stippling as well as teardrop poikilocytes may be present The leukocyte count may be normal reduced or increased If there is leukopenia there may be a uniform reduction in all the cells The blood may contain myelocytes and myeloblasts The platelet count may be normal or moderately reduced

However bone marrow punctures in various sites (sternum pelvic crest spinous processes) may be required before tumor cells are discovered Roentgenograms especially of the bones may be helpful and trephine biopsy of the marrow may be necessary If an enlarged lymph node is accessible it may be advisable to examine this microscopically and other procedures may need to be carried out in the search for malignancy A diagnosis of idiopathic aplastic anemia or of primary splenic panhematopenia" should be one of exclusion

Treatment will depend on the nature of the underlying disorder Blood transfusions are of temporary value in all the conditions which may produce this picture Ultimately if many transfusions are given hemochromatosis is produced since the iron from the transfused cells cannot be excreted Liver extract vitamin B_{12} folic acid and iron are of no value The temptation to remove an enlarged spleen must be tempered with good judgment This is especially important in those cases in which the spleen has assumed the function of the bone marrow for in such cases splenectomy can be harmful and at least is often of little or no value Nevertheless occasional patients derive definite benefit from splenectomy particularly when there is severe thrombocytopenia or increased blood destruction In cases in which large numbers of leukocytes in the circulating blood have been present roentgen therapy or chemotherapy such as that used in the treatment of chronic leukemia has been helpful

Green T W C L Conley L L Ashburn and H R Peters *Splenectomy for Myeloid Metaplasia of* the Spleen New Engl J Med 248 211 1953

Early in the disease the "shift to the left" is usually orderly with fewer metamyelocytes than segmented neutrophils fewer myelocytes than older forms and often few or no myeloblasts Later the myelocytes including the earlier forms tend to dominate the picture especially in the most advanced and more "acute" stages Eosinophils and basophilic leukocytes are likely to be found sometimes in substantial numbers If they are very numerous the terms *eosinophilic leukemia* and *basophilic leukemia* are appropriate The leukocyte count most often ranges between 100 000 and 500 000 cells per cubic millimeter when the disease is first discovered but values as great as 1 000 000 are sometimes seen Monocytes are present in normal or slightly increased numbers whereas lymphocytes though reduced in percentage maintain about a normal absolute value

The degree of anemia is a good index of the extent of the leukemic process In the earliest stages there is no anemia in far advanced cases it is profound The manner in which anemia is relieved when therapy reduces the extent of myeloid infiltration or becomes more severe as the disease advances gives support to the view that its cause is related to encroachment on the erythrocyte-forming elements by the leukemic cells The anemia is usually *normocytic in type* A few normoblasts are likely to be seen in the blood smear as well as slight polychromatophilia and occasional stippling

The platelets are normal in number or increased except in the terminal stages of the disease when *infiltration is very extensive* Then hemorrhagic manifestations prolonged bleeding time and other signs of secondary thrombocytopenic purpura are found In rare cases the platelet count may be extremely high and even megakaryocytes or fragments thereof may be found in the circulating blood

Chronic Lymphocytic Leukemia The onset is insidious as in the myelocytic form but the first symptom is likely to be painless enlargement of lymph nodes in the neck axilla or groin In other instances manifestations of anemia may dominate the picture and less commonly splenic enlargement or hemorrhagic manifestations may be the presenting complaints The skin is more often involved in the lymphocytic form than in the myelocytic as are also the gastrointestinal tract and the mediastinum There may be itching and burning with yellowish brown red bluish red or purple nodular skin lesions Bone tenderness is less frequent than in myelocytic leukemia The lymph nodes vary in size from that of a pea to that of a hen s egg and, though they are discrete several lying together may produce a huge mass They are moderately firm and smooth. Other manifestations are similar to those encountered in chronic myelocytic leukemia

The *blood picture* is that of a monotonous collection of small lymphocytes each looking just like its fellow contrasting strikingly with the colorful picture of myelocytic leukemia The leukocyte count more often ranges between 50 000 and 250 000 per cubic millimeter than at higher levels and 90 per cent or more of these cells are lymphocytes They often possess only a narrow rim of cytoplasm and may even appear to have none Larger lymphocytes may be seen but true "blast" forms with clearly defined nucleoli are unusual

As in myelocytic leukemia the presence or absence of anemia and its degree are good indexes of the extent of infiltration The anemia is normocytic and there may be occasional immature red cell forms in the blood smear Early the platelet count is normal as the disease advances it becomes greatly reduced and hemorrhagic manifestations may develop

Acute Leukemia The onset of acute leukemia is frequently rather abrupt and depending on the location and nature of the initial disturbance a great variety of clinical pictures may be encountered The initial symptoms may arise from leukemic infiltrations and glandular enlargement from hemorrhages or as the result of the systemic effects of the disease including those associated with anemia Sore throat abnormal bleeding from the mucous membranes or petechiae or ecchymoses in the skin cough or dyspnea resulting from enlargement of the thymus or mediastinal lymph nodes rheumatoid pains and a variety of neurologic complaints are among the manifestations which may be encountered Excessive bleeding following the extracting of a tooth or from minor injuries may be the first evidence of the disease Fever headache and general malaise may be soon followed by marked prostration and the onset of some severe malignantly virulent form of sepsis may be suspected

Lymph node enlargement is usually less conspicuous than in chronic leukemia but a systematic search will frequently reveal more or less generalized involvement of the lymph nodes The spleen is usually palpable but is rarely very large The liver is often enlarged The gums may be swollen and purplish in color and there may be ulceration in the mouth Sternal tenderness is present in the great majority of cases

The various types of acute leukemia cannot be differentiated on clinical grounds and this is often difficult even from the *blood examination* Anemia is practically always present when the disease is first discovered often it is severe The anemia is usually normocytic, *sometimes macrocytic* Poly

than once in a family is very small This seems strange when one considers the fact that suscepti bility to experimental leukemia and the transmission of the spontaneous disease in experimental animals follow definite genetic laws The explanation proba bly lies in the fact that although hereditary factors do exert an influence on the etiology of human leukemia as exemplified by familial cases of chronic lymphocytic leukemia especially their effect is modified by external influences and by other genes External factors include the effects of irradiation and perhaps also of trauma Leukemia has been described so much more often in persons exposed to radiation such as roentgenologists and those who were exposed to the atom bomb in Japan than in those not so exposed that this agent cannot be overlooked in a consideration of etiologic factors Not so well documented but nevertheless deserv ing serious consideration as *causes of leukemia* are trauma especially to bones and exposure to certain chemical agents especially benzol

The *cause* of leukemia is unknown The febrile character of acute leukemia and the evidences of infection about the mouth especially which can be seen in many cases have led some to hold the opinion that the disease is caused by an infectious agent Such a concept is difficult to accept in view of the fact that none of the other customary evi dences of infection have been observed such as transmission from man to man or from mother to fetus Experimental fowl leukemia it is true is carried by a filtrable agent but this is the case also with certain other types of neoplasms Newer knowledge is developing concerning the existence of transmissible cytoplasmic agents which deter mine the character of cells It is the more general view therefore that leukemia is neoplastic in char acter The transmission of experimental mammalian leukemia is generally thought to depend upon the transfer of viable cells In many cases of leukemia furthermore peculiarities can be observed in the leukemic cells which are like those of neoplastic cells including abnormal size and number of nucleoli and atypical as well as abnormal mitoses

Pathology The fundamental change in leukemia is widespread proliferation in the tissues and usu ally also in the blood stream of cells of a particular type In chronic myelocytic leukemia the bone mar row and spleen are chiefly involved but the lymph nodes liver kidneys lungs skin and other organs are also infiltrated The splenic pulp is full of myeloid cells and infarcts are commonly present In the chronic lymphocytic variety the lymphoid organs in particular show striking hyperplasia with disturbance of architecture and the liver bone marrow and other tissues are affected as well In acute leukemia the changes are similar and are ac companied by evidences of hemorrhage the result of the accompanying thrombocytopenia

CLINICAL MANIFESTATIONS

The clinical manifestations of the chronic and the acute leukemias differ from one another a great deal but there is comparatively little difference in the symptomatology of the various types of chronic leukemia and essentially no difference in the clini cal pictures of the different forms of acute leukemia

Chronic Myelocytic Leukemia The onset is in sidious and complaints may not develop until the disease has been in progress for a long time per haps a year or two The most common symptoms are those of anemia (weakness pallor palpitation or dyspnea) or a dragging sensation or swelling *in the left side of the abdomen due to the splenic* enlargement or complaints attributable to the in creased metabolic rate which develops as the disease progresses (loss of weight weakness nervousness cachexia etc) There may be slight fever rising as high as 101 F rarely higher As the disease advances the clinical picture may become more acute in that chills and fever may develop weight loss may become excessive and an abnormal tend ency to bleed may become manifest

The appearance of the patient ranges from that of seeming perfect health to one of extreme cachexia with marked pallor Splenomegaly is often the first physical sign of the disease The spleen may be just palpable or it may be huge the abdomen pro tuberant from this cause standing out in striking contrast to the general emaciation Lymph node enlargement is rarely significant but tenderness elicited on pressure over the lower portion of the sternum is a moderately early sign

Other symptoms and signs are less common but any system of the body can be affected The *liver* is often enlarged sometimes greatly and like the spleen is firm and not tender The *skin* may show small bluish gray elevated nodules due to specific infiltration The *retinas* may show hemorrhages and leukemic infiltrations There may be subperiosteal infiltration and even destructive lesions of *bone* leading to pathologic fractures Deafness from in filtration in the middle or inner ears or from hemor rhage evidences of nervous system involvement due to the same causes hematuria in association with infiltration of the kidney or other still less common manifestations may be observed Pain may develop from perisplenitis or in some cases pleural effusion may occur

The blood picture depends on the stage of the disease The earliest manifestation is leukocytosis due to an increase in the myeloid series of cells

similar to those seen in leukemia The term *erythroleukemia* refers to a very rare disorder in which there appears to be a combined neoplastic hyperplasia of both erythroblastic and leukoblastic tissues Cases such as these and lymphosarcoma cell leukemia plasma cell leukemia and cases of lymphocytic leukemia with only minor changes in the blood give support to the view now widely held that these conditions and those chiefly affecting lymph nodes such as lymphosarcoma as well as multiple myeloma are very closely related disorders or simply variations of a single abnormal process

DIAGNOSIS

The diagnosis of leukemia is not difficult in most cases Confusion may arise when the blood has not been examined thoroughly when the question of a leukemoid reaction arises or when the blood is subleukemic

Instances of chronic leukemia because of lymph node or splenic enlargement may suggest one of the various disorders affecting lymph nodes or the spleen (Chaps 219 and 220) or if the chief symptoms draw attention to other systems of the body a very great variety of conditions may be simulated Acute leukemia as already mentioned may suggest acute inflammatory conditions of various kinds purpura hemorrhagica or other disorders

Hematopoietic responses which suggest leukemia (*leukemoid pictures*) may be observed under a variety of circumstances

1 In association with *infections* A picture resembling myelogenous leukemia is sometimes associated with pneumococcal and meningococcal infections and rarely is seen in diphtheria and tuberculosis Lymphocytic leukemia may be suggested by the leukocytic reaction in whooping cough infectious mononucleosis and infectious lymphocytosis in particular and sometimes in chickenpox

2 *Intoxications* In rare instances of eclampsia severe burns diabetic acidosis and mercury poisoning leukemoid pictures have been observed

3 *Malignancy* especially with bone metastases as well as in multiple myeloma myelosclerosis and Hodgkin s disease

4 Following *severe hemorrhage or the rapid destruction of blood* when the profound stimulus to the bone marrow may bring forth a marked leukocytosis as well as immature forms of the nucleated red corpuscle series

The essential findings in the blood which favor leukemia rather than a leukemoid reaction are (1) pronounced immaturity of the leukocytes which is more significant than their number and (2) evidence of other hematopoietic disturbances which includes (*a*) anemia (*b*) the presence of immature red corpuscle forms in the blood such as nucleated red corpuscles and polychromatophilia and (*c*) platelet abnormalities especially thrombocytopenia Only in the early stages of chronic leukemia are anemia and other signs of disturbed hematopoiesis lacking In leukemia the immaturity of the leukocytes often is not orderly as in the case of a physiologic response where there are successively fewer numbers of the various immature forms with at most but a small number of myelocytes and but 1 or 2 per cent of myeloblasts

These criteria usually suffice to distinguish leukemia from a leukemoid reaction In addition the clinical findings such as splenomegaly lymphadenopathy and sternal tenderness make it apparent that one is dealing with leukemia On rare occasions however differentiation is quite difficult for the disease simulating leukemia may be accompanied by some of these physical signs and even immature forms of the red corpuscle series may find their way into the blood

In subleukemic leukemia especially and in the less clear instances where leukocytosis is present the *bone marrow* examination is very helpful for there abnormalities will usually be found which are well beyond the normal variations Only in the early stages of chronic lymphocytic leukemia or in the rare cases in which the marrow involvement is not diffuse is the sternal puncture likely to be disappointing In chronic myelocytic leukemia the cells in the bone marrow may be at a slightly less mature level than in the blood In acute myeloblastic leukemia even when there are few immature forms in the blood the marrow is crowded with myeloblasts In other types of acute leukemia the corresponding cells or their precursors will be found in large numbers in the marrow (see p 207)

Other examinations which may be helpful in reaching a diagnosis include *roentgenography* of the bones which may reveal subperiosteal infiltration osteolytic or tumorlike changes measurement of the *basal metabolic rate* which is increased in many cases of leukemia and sometimes lymph node biopsy

COURSE AND PROGNOSIS

With the possible exception of four instances there are no authentic reports of cure of leukemia In chronic leukemia the course is rarely interrupted by spontaneous remissions In acute leukemia such remissions are observed occasionally especially following infections and may last for several weeks The duration of life in cases of chronic leukemia varies greatly In some death ensues in a year or two after symptoms first appear in others the course may be extremely protracted extending over 10 or 15 years and very rarely even longer In certain cases such apparent long or short dura

chromatophilia as well as normoblasts is often found The platelet count is usually decreased at least to some degree even when the disease is first discovered The bleeding time then is prolonged the clot retracts poorly and the tourniquet test is positive

The leukocyte count rarely attains levels higher than 100 000 per cubic millimeter not infrequently it is below normal even below 1 000 At first glance the predominant cells are likely to be mistaken for lymphocytes Well stained thin smears are needed to demonstrate that the cells are abnormal and contain nucleoli When they are lymphoblasts or myeloblasts or even more immature forms (stem cells) they are difficult to distinguish from one another The nuclear differences are not easily recognized even by those with considerable experience and their cytoplasm is scanty and nongranular However in *acute myeloblastic leukemia* a small proportion of cells of slightly later development will often be found which will be seen to contain peroxidase positive granules Since such cells are lacking in *acute lymphoblastic leukemia* differentiation can sometimes be made on this basis *Acute monocytic leukemia* can be distinguished more easily however The pure and rarer form the *Schilling type* is characterized by the presence of large cells with lacy chromatin irregular nuclei inconspicuous nucleoli and irregular cell borders The cytoplasm contains innumerable very fine dustlike granules At the same time a few nongranular "blastlike" cells with nucleoli are found probably monoblasts In the *Naegeli type* of monocytic leukemia myelocytes are found in relatively large numbers in addition to cells resembling monocytes

Less Common Types of Leukemia *Subleukemic (Aleukemic) Leukemia* This term refers to those cases of leukemia of any type in which the leukocyte count is only slightly elevated normal or less than normal In such cases the abnormal cells may not predominate in the blood smear in fact they may be scarce and may not be readily discovered In most instances in which leukemic cells are stated to be absent however a good smear and stain and careful scrutiny by a person with some experience will usually reveal at least a few In any event the bone marrow contains a large number of the abnormal cells although sometimes they may be held together so firmly that they are not readily aspirated A normal or subnormal leukocyte count may be encountered at some stage of chronic or acute leukemia especially the latter This may be followed by a phase of leukocytosis or more often leukocytosis may be only a terminal event Sometimes leukocytosis never develops

Chloroma This term refers to a variant of acute leukemia which is characterized by the presence of greenish localized tumors connected particularly with the periosteum and ligamentous structures of the skull paranasal sinuses orbits spine ribs and sacrum Protrusion of an eyeball with diplopia and loss of vision pain deafness and signs of various cranial nerve palsies or other effects of pressure or infiltrative growth in a case otherwise consistent with a diagnosis of acute myeloblastic leukemia should lead to suspicion of chloroma

Chronic Monocytic Leukemia The great majority of cases of monocytic leukemia are acute or subacute as already described A small number are slower in their course Relatively low or subnormal leukocyte counts bone pain and cutaneous manifestations have characterized these cases

Lymphosarcoma Cell Leukemia The "lymphosarcoma cell" is about 9 to 14 μ in diameter has a sparse but deeply basophilic cytoplasm an oval oblong or kidney shaped nucleus with coarsely reticular spongy chromatin and a single prominent nucleolus Such cells are seen in cases fitting the category of "leukosarcoma" proposed by Sternberg Enlargement of lymph nodes in any one of many sites but especially in the anterior mediastinum or symptoms referable to anemia may for months or even years precede the appearance of these cells in the blood The leukocyte count may remain normal or low for a long time or even throughout the illness even though 30 to 98 per cent of the cells may ultimately be of the lymphosarcoma cell type

Plasma Cell Leukemia This term is applied to rare cases in which plasma cells have been found in the blood but which in other respects resemble leukemia—i e there is leukocytosis anemia and splenic and frequently lymph node and hepatic enlargement This disorder is perhaps but a variant of plasma cell myeloma but in contrast to typical multiple myeloma (Chap 221) bone involvement and hyperproteinemia may not be present There may be extraosseous plasmacytomas in the upper respiratory passages the cornea the pleura and elsewhere

A number of other still more rare forms of leukemia have been described They include so called megakaryocytic and acute megakaryoblastic leukemia eosinophilic leukemia and basophilic or mast cell leukemia The clinical course of some cases of eosinophilic leukemia is so unlike that of myelocytic leukemia that in some instances one wonders whether they represent true leukemia *Acute and chronic erythremic myelosis* refers to a disorder in which the erythropoietic tissue rather than the leukopoietic tissue seems to be involved in a neoplastic process The blood contains numerous erythroblasts in all stages of maturation but the most immature forms are found in disproportionately large numbers Other manifestations are

similar to those seen in leukemia The term *erythroleukemia* refers to a very rare disorder in which there appears to be a combined neoplastic hyperplasia of both erythroblastic and leukoblastic tissues Cases such as these and lymphosarcoma cell leukemia plasma cell leukemia and cases of lymphocytic leukemia with only minor changes in the blood give support to the view now widely held that these conditions and those chiefly affecting lymph nodes such as lymphosarcoma as well as multiple myeloma are very closely related disorders or simply variations of a single abnormal process

DIAGNOSIS

The diagnosis of leukemia is not difficult in most cases Confusion may arise when the blood has not been examined thoroughly when the question of a leukemoid reaction arises or when the blood is subleukemic

Instances of chronic leukemia because of lymph node or splenic enlargement may suggest one of the various disorders affecting lymph nodes or the spleen (Chaps 219 and 220) or if the chief symptoms draw attention to other systems of the body a very great variety of conditions may be simulated Acute leukemia as already mentioned may suggest acute inflammatory conditions of various kinds purpura hemorrhagica or other disorders

Hematopoietic responses which suggest leukemia (*leukemoid pictures*) may be observed under a variety of circumstances

1 In association with *infections* A picture resembling myelogenous leukemia is sometimes associated with pneumococcal and meningococcal infections and rarely is seen in diphtheria and tuberculosis Lymphocytic leukemia may be suggested by the leukocytic reaction in whooping cough infectious mononucleosis and infectious lymphocytosis in particular and sometimes in chickenpox

2 *Intoxications* In rare instances of eclampsia severe burns diabetic acidosis and mercury poisoning leukemoid pictures have been observed

3 *Malignancy* especially with bone metastases as well as in multiple myeloma myelosclerosis and Hodgkin s disease

4 Following *severe hemorrhage or the rapid destruction of blood* when the profound stimulus to the bone marrow may bring forth a marked leukocytosis as well as immature forms of the nucleated red corpuscle series

The essential findings in the blood which favor leukemia rather than a leukemoid reaction are (1) pronounced immaturity of the leukocytes which is more significant than their number and (2) evidence of other hematopoietic disturbances which includes (*a*) anemia (*b*) the presence of immature red corpuscle forms in the blood such as nucleated red corpuscles and polychromatophilia and (*c*) platelet abnormalities especially thrombocytopenia Only in the early stages of chronic leukemia are anemia and other signs of disturbed hematopoiesis lacking In leukemia the immaturity of the leukocytes often is not orderly as in the case of a physiologic response where there are successively fewer numbers of the various immature forms with at most but a small number of myelocytes and but 1 or 2 per cent of myeloblasts

These criteria usually suffice to distinguish leukemia from a leukemoid reaction In addition the clinical findings such as splenomegaly lymphadenopathy and sternal tenderness make it apparent that one is dealing with leukemia On rare occasions however differentiation is quite difficult for the disease simulating leukemia may be accompanied by some of these physical signs and even immature forms of the red corpuscle series may find their way into the blood

In subleukemic leukemia especially and in the less clear instances where leukocytosis is present *the bone marrow* examination is very *helpful* for there abnormalities will usually be found which are well beyond the normal variations Only in the early stages of chronic lymphocytic leukemia or in the rare cases in which the marrow involvement is not diffuse is the sternal puncture likely to be disappointing In chronic myelocytic leukemia the cells in the bone marrow may be at a slightly less mature level than in the blood In acute myeloblastic leukemia even when there are few immature forms in the blood the marrow is crowded with myeloblasts In other types of acute leukemia the corresponding cells or their precursors will be found in large numbers in the marrow (see p 207)

Other examinations which may be helpful in reaching a diagnosis include *roentgenography* of the bones which may reveal subperiosteal infiltration osteolytic or tumorlike changes measurement of the *basal metabolic rate* which is increased in many cases of leukemia and sometimes lymph node biopsy

COURSE AND PROGNOSIS

With the possible exception of four instances there are no authentic reports of cure of leukemia In chronic leukemia the course is rarely interrupted by spontaneous remissions In acute leukemia such remissions are observed occasionally especially following *infections and may last for several weeks* The duration of life in cases of chronic leukemia varies greatly In some death ensues in a year or two after symptoms first appear in others the course may be extremely protracted extending over 10 or 15 years and very rarely even longer In certain cases such apparent long or short dura

tion depends respectively upon early diagnosis or late discovery of the disease In most instances the essential factor probably consists in different intensities of the pathologic process The average duration of life in chronic leukemia of all varieties is 3¼ years It is thought that about 12 per cent of cases survive more than 5 years For acute leukemia available statistics vary but in the largest series which has been studied the mean survival time from the onset of symptoms was 20 3 weeks in patients treated only with transfusions and antibiotics The longest was 58 weeks but 50 per cent of the patients were dead within 17 weeks 90 per cent within 36 weeks

In chronic leukemia treatment even though it may not increase survival time by more than 6 months or a year can for much of the time make the difference between a state of chronic invalidism and a condition of well being which may approach normality In acute leukemia the newer methods of treatment have made it possible in many instances to bring about and maintain remission in children for significant periods of time and perhaps also to prolong life In adults the results of treatment in most cases have been much less satisfactory

Prognosis in chronic leukemia can be judged more from the degree of anemia and the extent of weight loss than from the magnitude of the leukocyte count especially if these fail to respond following therapy Thrombocytopenia is also an unfavorable sign for except in occasional cases of chronic myelocytic leukemia this indicates extensive infiltration of a degree not likely to be greatly influenced by treatment

TREATMENT

Although cure of leukemia has not been achieved as yet present day methods of therapy provide considerable improvement reduce morbidity and may even prolong life as outlined above In addition to irradiation and chemotherapy which will be considered below *general measures* of management are important These include blood transfusions when necessary and antibiotics The latter are often not needed if only leukopenia is present they are better reserved for prompt use at the first sign of infection Good oral hygiene is important as well as a well balanced nourishing diet Advice concerning rest and activity should be guided by the make up of the patient In general patients with leukemia should be encouraged to maintain their normal activities in so far as possible treatment should be provided with the object of reducing morbidity and hospitalization should be reduced to a minimum

Irradiation This is of value in chronic leukemia and may be given by means of roentgen rays radioactive phosphorus (P³) *radium thorium* X or mesothorium Only the first two are now used *Increasing anemia loss of weight pressure symptoms* invasion of tissues with production of pain or disfiguring or uncomfortable glandular enlargement are indications for treatment These are of more importance than a high or rising leukocyte count While hemorrhagic manifestations and thrombocytopenia like anemia may be due to marrow infiltration by leukemic cells and thus may be alleviated by treatment more often they are part of the terminal picture of chronic leukemia and indicate that *treatment is likely to be ineffective* Acute leukemia is another contraindication to irradiation Such treatment is not only of little or no value but may be harmful

Although roentgen therapy has been the generally accepted form of *radiation therapy the choice between* this and treatment with P³ is mainly a matter of availability and convenience The details of dosage are matters for the specialist Serial daily doses of 100 to 200 r or as little as 25 to 50 r appropriately filtered and over specified areas are used by various workers Treatment is stopped when the leukocyte count has fallen to approximately 25 000 per cubic millimeter but this is not an absolute criterion since irradiation given cautiously may prove effective even in cases with leukopenia

Treatment with phosphorus made radioactive (P³) offers the advantage that the radioactive material is concentrated in the position where it is especially required—that is in those tissues which have a high phosphorus content and metabolize phosphorus rapidly the liver spleen kidneys and bone marrow The material can be given orally or intravenously and unlike roentgen irradiation it does not result in radiation sickness

There is good evidence that actual prolongation of life can be achieved with regularly spaced irradiation designed to keep the patient in a good state of health and at his normal occupation There are few now who hold to the view that irradiation *therapy or chemotherapy for that matter* should be reserved for use only in well established relapse or when symptoms are prominent

Chemotherapy Chemotherapy besides being less expensive than roentgen ray therapy as a rule makes management practical for those patients who do not reside where roentgen therapy apparatus is available Many roentgenologists employ daily treatments for 2 to 3 weeks which may be inconvenient as well as expensive in some cases A variety of chemotherapeutic agents is now available which can be taken orally Observations on *patients treated* with such agents may be spaced at intervals of one to several weeks thus permitting a return to normal activities and reducing cost In the last analysis however treatment must be designed to suit the individual needs of the patient d often both

Table 108 RELATIVE VALUE OF DIFFERENT AGENTS IN TREATMENT OF LEUKEMIAS AND LYMPHOMAS

6-Mercaptopurine	+	0	+++	++	+++	0	0

irradiation and chemotherapy are required at different times in the same person Thus disfiguring and uncomfortable adenopathy or great splenomegaly may call for local roentgen therapy whereas systemic manifestations are well handled by chemotherapy or radioactive phosphorus

In general the chemotherapeutic agents useful in the treatment of chronic leukemia differ from those valuable in acute leukemia (Table 108)

Chronic Leukemia Chemotherapeutic agents include Myleran (a sulfonic acid ester 1 4 dimethanesulfonyloxybutane) demecolcin (desacetyl methylcolchicine) chlorambucil [*p* (di 2 chloroethyl) aminophenylbutyric acid] and triethylene melamine

Although the nausea and vomiting associated with *nitrogen mustard* therapy (p 1226) can be allayed considerably by sedatives or an antiemetic such as chlorpromazine the discovery of other agents equally or more effective without such unpleasant action makes it unnecessary to use this drug Similar to nitrogen mustard in pharmacologic effects is *triethylenemelamine* which can be given orally and rarely causes gastrointestinal symptoms This agent is a potent hematopoietic depressant and must be used with great caution It is most useful in chronic lymphocytic leukemia For the myelocytic variety other less toxic agents are available Daily administration for a week or more seems unwise since the depressant effect is cumulative It is better to give the agent over a period of 1 to 3 days waiting then for 2 or 3 weeks before more is given so that its full effect can be determined As little as 1 or 2 mg may produce a fall in the leukocyte count and reduction in lymphadenopathy in chronic lymphocytic leukemia although 5 and rarely even 10 mg may be required The drug is usually given on awakening in the morning together with 2 Gm sodium bicarbonate Breakfast may be taken 2 hr later

Also useful in the treatment of chronic lymphocytic leukemia is *chlorambucil* an aromatic mustard 0 1 mg/kg/day by mouth This agent may be less toxic than triethylenemelamine

Myleran appears to be the most useful of the chemotherapeutic agents for chronic myelocytic leukemia In oral doses of 4 to 6 mg daily its use is associated with a reduction in the leukocyte count in the course of several weeks and a rise in hemoglobin together with corresponding clinical improvement Thrombocytopenia and purpura are the chief toxic manifestations but these are uncommon Only rarely is there any gastric discomfort When the leukocyte count has decreased to approximately 10 000 per cubic millimeter treatment is stopped Remissions measured in months have been observed Demecolcin Colcemide (an alkaloid isolated from colchicum) also is effective in chronic myelocytic leukemia The oral dose is 4 to 6 mg daily However relapse occurs promptly unless the drug is continued

Urethan 1 to 6 Gm daily by mouth has proved to be of value in many cases of chronic myelocytic leukemia but is much less useful than Myleran Nausea and anorexia may be produced by the drug The amount which is required to achieve clinical improvement may total 150 Gm However smaller amounts (0 5 to 2 Gm daily) will serve for maintenance therapy or the drug may be given intermittently

These agents as already indicated will bring symptomatic relief in many cases of chronic leukemia lymph nodes will decrease in size the spleen will become smaller anemia will decrease or dis

appear weight will be gained and a sense of well being will return to remain for variable lengths of time For the treatment of chronic lymphocytic leukemia chlorambucil is perhaps the best of the chemotherapeutic agents available at present For chronic myelocytic leukemia Myleran is the most satisfactory drug but Colcemide is sometimes effective when Myleran fails They have little value in the lymphocytic form

Splenectomy has been helpful in occasional cases of chronic lymphocytic leukemia when there was severe anemia associated with a reduced survival time of transfused red corpuscles even in the absence of frank signs of hemolytic anemia In such cases the steroid hormones cortisone and prednisone and adrenocorticotropic hormone have also been useful and they should therefore be given a trial before splenectomy is considered

Acute Leukemia In acute leukemia roentgen therapy is of no value radioactive phosphorus has limited application and the above mentioned chemotherapeutic agents are of no benefit Nitrogen mustard will reduce the leukocyte count and may relieve bone pain but offers nothing more On the other hand the steroid hormones the folic acid antagonists and other agents such as 6 mercapto purine are valuable in many cases

The steroid hormones of which *prednisone* and *cortisone* are preferable since they can be adminis tered by mouth have been found to bring about a remission in approximately two thirds of the cases of acute lymphoblastic leukemia in children and perhaps in half this proportion of adults To achieve these results usually a dose must be given which is large enough to produce signs of hyper corticism generally 100 to 200 mg cortisone or 40 to 60 mg prednisone daily Such treatment should be supplemented by potassium chloride (2 to 6 Gm daily) and the diet must be salt free A similar beneficial effect is not observed in myelo blastic or monocytic leukemia in fact these types may even be made worse Once a remission has been attained steroid therapy is stopped The re-mission may last several weeks or sometimes months One may attempt to prolong the remission by the administration of a folic acid antagonist Re treatment with steroid hormones may produce a second remission but this is usually less complete than the first

A variety of folic acid antagonists is available but *Amethopterin* (Methotrexate 4 amino N[10] methylpteroylglutamic acid) and *Aminopterin* (4 aminopteroylglutamic acid) are more generally em ployed The daily oral dose range of Amethopterin is 1 25 to 5 0 mg rarely more while that of Amino pterin is 0 5 to 2 mg The drug is given until a remission has been produced or severe toxic symp toms occur oral ulceration anorexia nausea vomiting and diarrhea leukopenia increasing thrombocytopenia and hemorrhage and increasing anemia alopecia and skin rash Sometimes it is very difficult to distinguish between toxic effects and an increase in the signs of leukemia When given in large enough doses the antagonists will lead to the appearance of megaloblasts in the bone marrow In children with Amethopterin as with cortisone remissions have been observed in approxi mately 60 per cent of those treated in adults these agents are much less successful Ultimately *resistance develops in all cases and the drugs be* come no longer effective

Of the other analogs of folic acid purines py rimidines and amino acids which have been studied with the object of discovering additional anti leukemic agents 6 *mercaptopurine* (6MP Purine thol) is the most clearly useful agent Good clin ical and hematologic remissions have been observed in somewhat less than 50 per cent of children with acute leukemia and in about 25 per cent of adults Remissions have lasted from 1 to 10 months and have been observed even in patients who had be come resistant to folic acid antagonists or to the steroids The usual therapeutic dose is 2 5 mg per kg body weight per day by mouth Sometimes twice this amount is given for a short time but in such cases the danger of producing marrow hypoplasia must be kept in mind This drug has also been found to produce improvement in early chronic myelocytic leukemia and occasional beneficial ef fects have been observed in the terminal acute stage of chronic myelocytic leukemia Such remis sions however have usually been of short duration

The most effective method for the treatment of acute leukemia is to use one agent at a time and to follow this with another one of the agents which has been shown to be effective Thus in the man agement of a case of acute lymphoblastic leukemia one might initiate treatment with steroids this be ing continued until a remission has been produced Therapy is then interrupted and the patient is observed at weekly or fortnightly intervals until the first suggestion of relapse appears Many give main tenance therapy with one of the chemotherapeutic agents but the need for this has not been proved convincingly When beginning anemia thrombo cytopenia fever sternal tenderness an occasional immature leukocyte in the blood or any other evi dence of beginning relapse appears either a folic acid antagonist or 6MP is administered until a new remission has been achieved If the remission is complete treatment may be again interrupted and is resumed when evidence of relapse once again be gins to appear this time the third agent either Amethopterin or 6 mercaptopurine being used

Later still any one of these agents may be tried again By such a plan of alternating use of drugs the development of "resistance" to one of these agents may possibly be delayed and it may be possible to prolong the life of the patient In cases of acute myeloblastic or monocytic leukemia the steroid hormones are of no value as already mentioned and treatment must depend on the antifolic acid compounds and 6-mercaptopurine The chief merit of still other agents now under study such as azaserine is that they may be employed either alone or together with the more promising drugs when the latter have spent their usefulness

219 DISEASES OF THE SPLEEN AND RETICULOENDOTHELIAL SYSTEM

M M Wintrobe

The functions of the spleen were outlined in an earlier chapter (p 225) Disorders of the spleen most frequently produce enlargement of this organ The significance of splenic enlargement has been considered already and the differential diagnosis of splenomegaly was discussed there (p 226) Here several of the disorders which involve the spleen in particular will be described

Disorders of the spleen not hitherto considered include congenital anomalies rupture and infarction *Congenital anomalies* may take various forms Instead of being a single organ, the spleen may be subdivided into numerous small spleens or a spleen of normal size and shape may be accompanied by one or more accessory spleens Rarely the spleen assumes a retroperitoneal position and may force the left kidney downward A *movable* spleen may be found in any part of the abdomen If its pedicle becomes twisted there may be sudden pain, enlargement and signs of shock, as well as fever and vomiting if the torsion has developed acutely Less severe symptoms occur if the process is more gradual

Rupture of the spleen may occur following trauma particularly if the spleen is diseased Malaria typhoid fever and infectious mononucleosis are among the diseases in which this has been observed Agonizing abdominal pain or pain in the left scapular region, together with signs of internal hemorrhage characterize this catastrophe Anemia develops rapidly and leukocytosis occurs Prompt surgical treatment is imperative After traumatic rupture autotransplantation of splenic tissue (*splenosis*) sometimes occurs

Infarction of the spleen may be sterile in which event it is followed eventually by fibrosis and shrinkage This has been observed as a complication of leukemia A septic infarct may terminate with the formation of an abscess The most common symptom of infarction is pain Careful examination will reveal a friction rub Unless an abscess forms necessitating surgical intervention, sedation and abdominal support to impair movement of the spleen suffice

Congenital absence of the spleen may be suspected when Howell Jolly bodies occasional nucleated red cells target cells decreased osmotic fragility siderocytosis leukocytosis and a variable degree of thrombocytosis are found in the absence of a discoverable cause and particularly when there

is associated congenital heart or intestinal malformation

CHRONIC CONGESTIVE SPLENOMEGALY

Definition This syndrome also called Banti s syndrome or splenic anemia is characterized by splenic enlargement leukopenia anemia and often thrombocytopenia a tendency to gastric hemorrhage and in many cases cirrhotic changes in the liver

History The term *splenic anemia* was originally used (1866) to refer to cases of anemia with splenomegaly which were not frank leukemia Banti in 1882 and subsequently described a form of splenomegaly of unknown etiology associated in its earliest stages with leukopenia asthenia and occasional hemorrhagic episodes In the intermediary stage hepatic enlargement occurred as well as urobilinuria and a dirty brownish discoloration of the skin The final stage consisted of liver atrophy and ascites

Etiology Banti described the spleen as being characterized by conspicuous thickening of the fibrillar reticulum in the Malpighian corpuscles and red pulp (fibro adenie) These changes originated around the central artery of the follicle In his opinion the spleen was the primary seat of the disease Later work showed that these changes are not specific and can be encountered particularly when there is increased venous pressure in the portal bed Thus the designation *chronic congestive splenomegaly* has arisen Cirrhosis of the liver cavernous transformation of the portal vein portal vein and splenic vein thrombosis or variants in the anatomy of the venous pattern have been found in as many as 60 per cent of the cases Active congestion in the spleen in the absence of venous obstruction has also been proposed as a cause of this syndrome This concept depends on the hypothesis that disease of the splenic arteries is the primary fault with the result that they fail to control the amount of blood entering the spleen thus permitting congestion to develop

Pathology The spleen weighs 600 to 1 200 Gm as a rule but may weigh as much as 5 000 Gm At first one finds an increase in the reticulum cellular hyperplastic pulp degenerative changes in the follicular arterioles and congestion Later the follicles become smaller while fibrosis of the reticulum trabeculae and capsule increases Periarterial hemorrhages and siderotic nodules deposited in the fibrous tissue around the arterioles are found in many instances

Symptoms Young adults are most frequently affected but the disease may come on in childhood The onset is usually insidious The condition may ultimately attract attention in a variety of ways There may be gastrointestinal complaints of vague character probably attributable to the large mass in the left upper quadrant the mass itself may be noticed accidentally symptoms of anemia may become prominent or the disorder may be announced explosively by the occurrence of a gastric hemorrhage The spleen may extend to the pelvic brim Ultimately the symptoms and signs of cirrhosis of the liver appear Obstruction of mesenteric veins may lead to the development of hemorrhoids while occlusion of the portal vein is followed by the appearance of signs of collateral circulation

The anemia is normocytic and moderate in degree unless hemorrhage has occurred when it may be microcytic hypochromic in type In cases with long standing and severe liver disease the anemia may be macrocytic Leukopenia is found consistently and thrombocytopenia is observed frequently The bone marrow may show no abnormality or slight myeloid hyperplasia may be present

Diagnosis Other conditions leading to pancytopenia (p 1210) must be excluded Hereditary spherocytosis is not associated with leukopenia as a rule and may be distinguished also by the finding of reticulocytosis increased hypotonic saline fragility and the presence of spherocytes Hookworm infection may produce chronic hypochromic anemia with moderate splenomegaly Liver function should be studied in suspected cases and esophageal varices looked for If liver function is good and other conditions have been excluded portal or splenic vein thrombosis should be suspected Congestive splenomegaly due to extrahepatic causes is more likely to be found in patients below the age of eighteen than in older patients

Prognosis and Treatment Unless serious hemorrhage ensues the course of the disease is slow as a rule and relatively benign Patients may live for 10 years or longer The chief nonsurgical procedures are administration of a diet rich in protein and otherwise complete as well administration of iron if there has been hemorrhage and blood transfusion if bleeding has occurred recently If there is gastroesophageal bleeding abdominal exploration is advisable since some cause for congestion in the portal bed may be discovered and treated At one time splenectomy was the sole surgical measure employed However although this procedure is likely to relieve the leukopenia—and thrombocytopenia if it is present—it is of little value in relieving the portal hypertension Now therefore it is considered that a surgeon should not perform splenectomy in congestive splenomegaly unless he is prepared to form a venovenous anastomosis with the object of reducing the increased pressure in the portal bed Portacaval shunt is usually preferred because of the large size of the vessels involved If

a large-caliber splenic vein is available or when the portal vein is obliterated splenectomy and splenorenal shunts are recommended When an adequate shunt cannot be made esophagogastrectomy is employed Following removal of the spleen the leukopenia disappears the anemia is relieved in whole or in part and the platelet count is also likely to be restored to normal

GAUCHER S DISEASE

Definition This is a rare chronic familial disorder characterized by marked splenomegaly and often also by skin pigmentation pinguecular of the scleras and bone lesions

Etiology Morbid Anatomy and Pathogenesis The disorder usually is apparent early in life It has a predilection for females and the condition has been observed most often in Jewish families The characteristic finding is widespread reticulum cell hyperplasia these cells being filled with kerasin Consequently Gaucher s disease is classed as a disturbance of lipoid metabolism The cause is unknown The cells are distinctive being 20 to 80 μ in diameter round oval or spindle shaped and possessing one or more small eccentrically placed nuclei Appropriately stained the cytoplasm shows numerous wavy fibrillae These cells are found in the spleen, bone marrow lymph nodes and liver The spleen may weigh as much as several thousand grams

Symptoms The enlargement of the spleen is usually the outstanding manifestation sometimes the only one There may be a dragging sensation or pain due to infarction Pain in the limbs due to bone involvement may develop The liver may be enlarged but the lymph nodes usually are not palpable Roentgenograms may reveal osseous changes Hemorrhage from the nose or gums is relatively common Light yellowish brown discolorations on the conjunctivas on either side of the cornea and an ocher-to-brown hue of the skin, may be present.

As in other splenic disorders moderate anemia, leukopenia and thrombocytopenia are the usual blood findings

Diagnosis Diagnosis can be made by sternal or splenic puncture which will reveal the characteristic cells

Treatment and Prognosis Although the disease coincidently involves other parts of the reticuloendothelial system splenectomy is worthwhile if the spleen is very large and thereby causes discomfort or if there are serious symptoms attributable to the blood changes In infants the prognosis is not good but those who have survived to adolescence may live for many years even if splenectomy is not performed

NIEMANN PICK DISEASE

This is a lipoid disorder of the reticuloendothelial system very similar to Gaucher s disease except that the condition has been observed only in infancy and its course is much more acute death occurring within a few months after birth The characteristic cells are filled with small round hyaline droplets grouped in clusters and giving the appearance of a honeycomb The stored material is a phospholipid, perhaps sphingomyelin

HAND SCHULLER-CHRISTIAN DISEASE

Exophthalmos diabetes insipidus and defects in the membranous bones form the triad which characterizes Hand Schuller Christian disease At one time the manifestations of this disorder were considered to be produced by the growth of a characteristic type of granulation tissue with cells containing cholesterol and it esters The present tendency is to regard Schuller Christian disease as being closely related to Letterer Siwe disease and to eosinophilic granuloma *Eosinophilic granuloma* is a disorder localized to bone consisting of solitary or multiple osteolytic lesions but with no discernible visceral involvement It is found in infants children and young adults and occasionally at a later age and is treated satisfactorily by curettement or roentgen therapy *Letterer Siwe disease* has been observed exclusively in infants and young children, is variable in duration (a few weeks to several years) and has been almost uniformly fatal The three conditions possess as a common denominator a distinctive inflammatory histiocytosis Some regard Letterer Siwe disease as the acute or subacute form of a disorder of which the Schüller Christian picture is the chronic counterpart The onset of the latter is in children and in young adults The histiocytosis or granulomatosis may or may not be accompanied by intense eosinophilic reaction the characteristic lipogranuloma is now thought to be the late phase in the evolution of the histiocytic lesion Unlike Gaucher s disease and Niemann Pick disease there is no family predilection and splenomegaly and hepatomegaly do not always occur and are never conspicuous The blood may show pancytopenia Death may not ensue for many years but considerable disability may occur in the interval

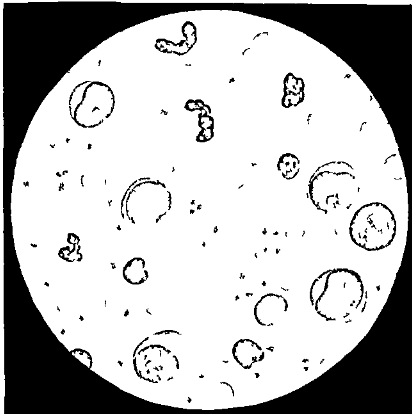
220 HODGKIN S DISEASE AND OTHER "LYMPHOMAS

M M Wintrobe

In an earlier chapter (p 223) the causes of lymph node enlargement were discussed and their differential diagnosis was considered In this section *the clinical manifestations of Hodgkin s disease and* of other conditions chiefly affecting lymph nodes such as lymphosarcoma will be described These disorders will be considered under one heading because their clinical manifestations are very similar

Definition Hodgkin s disease lymphosarcoma giant follicular lymphoblastoma (lymphoma) and reticulum cell sarcoma are included in this group They are characterized by painless progressive enlargement of lymphoid tissue Lymphadenopathy is a characteristic feature and the spleen is frequently enlarged Cachexia anemia and in many *instances fever usually are late symptoms*

History A disorder affecting the absorbent glands and spleen" was described by Hodgkin in 1832 *Lymphoblastoma malignant lymphogranuloma* and many other terms were used in referring to the disease in subsequent descriptions Jackson and Parker attempted to classify the disorder in three categories—paragranuloma granuloma and Hodgkin s sarcoma The picture of lymphosarcoma was described by Kundrat in 1893 while Brill Baehr and Rosenthal differentiated giant follicular lymphoblastoma in 1925 Roulet (1932) separated reticulum cell sarcoma from the general group of *malignant diseases of lymphoid tissue Some pa*thologists differentiate still other groups or call these by other names others seek to avoid fine separations



Classification Clinically these disorders vary considerably in severity Histologically they show marked differences but these are not well correlated with the clinical picture They have been classified in various ways on histologic grounds *One of the most simple is that which differentiates* those conditions with a simple histologic pattern from those with more complex patterns In the first category are reticulum cell sarcoma and lymphosarcoma The proliferating cells tend to encroach upon obscure and finally replace the architecture of the lymph node The histologic pattern of Hodgkin s disease is more complex Lymphocytes plasma cells granulocytes (eosinophilic and neutrophilic) monocytes fibroblasts and giant cells make up the picture The giant Reed Sternberg cells 10 to 40 μ in diameter are possessed of abundant cytoplasm a multilobed nucleus or multiple nuclei and prominent nucleoli A variable amount of fibrosis may be present and the lymph node architecture is often lost In giant follicular lymphoma the histologic pattern is also somewhat complex but the striking feature is the presence of multiple folliclelike nodules of various sizes Other types of lymphoma" *are observed from time to time which are difficult to classify*

Etiology Hodgkin s disease forms about one third to one half of all cases of this group It affects a younger age group than the other conditions being most common in the second and third decades However no age is immune Males are more frequently affected than females

The cause of these disorders is unknown There may not even be the common denominator of neoplastic growth to unite them for many investigators consider Hodgkin s disease to be an infectious granuloma Efforts to transmit the disease to animals have failed however and attempts to incriminate various organisms including the tubercle bacillus human and avian diphtheroid bacilli and *Brucella* organisms have not succeeded An agent *in the lymph nodes found to produce encephalitis* on inoculation into animals appears to be a nonspecific chemical substance derived most probably from eosinophilic leukocytes The other disorders in this group are assumed generally to be true neoplasms This applies even to giant follicular lymphoma which at first was considered a benign disease

Symptoms In most cases lymph node enlargement usually cervical is the first symptom to attract attention This may be bilateral but is more often unilateral at first More rarely the axillary or the inguinal nodes are the first to enlarge The *nodes are discrete and movable at first* only later do they become matted together and fixed As a rule they are painless and not tender and the overlying skin is normal However when they have developed rapidly or when nerves are infiltrated as well they may be painful This is true in Hodgkin s disease especially The size of the nodes ranges from that of a pea to that of a large orange There is a resilient firmness in most instances but the *growth of connective tissue may make the nodes of* Hodgkin s disease harder in the course of time Occasionally the nodes in the axillary or inguinal regions may become secondarily inflamed and even break down

After an interval varying from months to years evidence appears of lymph node involvement elsewhere This may affect other superficial nodes

220 HODGKIN S DISEASE AND OTHER LYMPHOMAS

M M Wintrobe

In an earlier chapter (p 223) the causes of lymph node enlargement were discussed and their differential diagnosis was considered In this section the clinical manifestations of Hodgkin s disease and of other conditions chiefly affecting lymph nodes such as lymphosarcoma will be described These disorders will be considered under one heading because their clinical manifestations are very similar

Definition Hodgkin s disease lymphosarcoma giant follicular lymphoblastoma (lymphoma) and reticulum cell sarcoma are included in this group They are characterized by painless progressive enlargement of lymphoid tissue Lymphadenopathy is a characteristic feature and the spleen is frequently enlarged Cachexia anemia and in many instances fever usually are late symptoms

History A disorder affecting the absorbent glands and spleen was described by Hodgkin in 1832 *Lymphoblastoma malignant lymphogranuloma* and many other terms were used in referring to the disease in subsequent descriptions Jackson and Parker attempted to classify the disorder in three categories—paragranuloma granuloma and Hodgkin s sarcoma The picture of lymphosarcoma was described by Kundrat in 1893 while Brill Baehr and Rosenthal differentiated giant follicular lymphoblastoma in 1925 Roulet (1932) separated reticulum cell sarcoma from the general group of malignant diseases of lymphoid tissue Some pathologists differentiate still other groups or call these by other names others seek to avoid fine separations

Classification Clinically these disorders vary considerably in severity Histologically they show marked differences but these are not well correlated with the clinical picture They have been classified in various ways on histologic grounds One of the most simple is that which differentiates those conditions with a simple histologic pattern from those with more complex patterns In the first category are reticulum cell sarcoma and lymphosarcoma The proliferating cells tend to encroach upon obscure and finally replace the architecture of the lymph node The histologic pattern of Hodgkin s disease is more complex Lymphocytes plasma cells granulocytes (eosinophilic and neutrophilic) monocytes fibroblasts and giant cells make up the picture The giant Reed Sternberg cells 10 to 40 μ in diameter are possessed of abundant cytoplasm a multilobed nucleus or multiple nuclei and prominent nucleoli A variable amount of fibrosis may be present and the lymph node architecture is often lost In giant follicular lymphoma the histologic pattern is also somewhat complex but the striking feature is the presence of multiple folliclelike nodules of various sizes Other types of lymphoma are observed from time to time which are difficult to classify

Etiology Hodgkin s disease forms about one third to one half of all cases of this group It affects a younger age group than the other conditions being most common in the second and third decades However no age is immune Males are more frequently affected than females

The cause of these disorders is unknown There may not even be the common denominator of neoplastic growth to unite them for many investigators consider Hodgkin s disease to be an infectious granuloma Efforts to transmit the disease to animals have failed however and attempts to incriminate various organisms including the tubercle bacillus human and avian diphtheroid bacilli and *Brucella* organisms have not succeeded An agent in the lymph nodes found to produce encephalitis on inoculation into animals appears to be a nonspecific chemical substance derived most probably from eosinophilic leukocytes The other disorders in this group are assumed generally to be true neoplasms This applies even to giant follicular lymphoma which at first was considered a benign disease

Symptoms In most cases lymph node enlargement usually cervical is the first symptom to attract attention This may be bilateral but is more often unilateral at first More rarely the axillary or the inguinal nodes are the first to enlarge The nodes are discrete and movable at first only later do they become matted together and fixed As a rule they are painless and not tender and the overlying skin is normal However when they have developed rapidly or when nerves are infiltrated as well they may be painful This is true in Hodgkin s disease especially The size of the nodes ranges from that of a pea to that of a large orange There is a resilient firmness in most instances but the growth of connective tissue may make the nodes of Hodgkin s disease harder in the course of time Occasionally the nodes in the axillary or inguinal regions may become secondarily inflamed and even break down

After an interval varying from months to years evidence appears of lymph node involvement elsewhere This may affect other superficial nodes

supraclavicular axillary inguinal subpectoral brachial or femoral A common site also is the mediastinum to which such symptoms as cough dyspnea stridor or dysphagia should attract attention Splenomegaly develops in more than half the cases of Hodgkin s disease and of giant follicular lymphoma less frequently in the other forms The liver is often palpable Ultimately cachexia develops and weight loss occurs

The mode of onset of these disorders may vary greatly however The manifestations may arise first in the mediastinum the lungs the digestive tract the genitourinary tract the bones and rarely the nervous system Infiltration of the lungs atelectasis or pleural effusion may occur In the gastrointestinal tract the tumor may be far advanced before it is first discovered Colicky pain loss of weight anemia a palpable tumor and obstruction are signs produced by lymphosarcoma of the small intestine When the retroperitoneal nodes are the chief ones to enlarge the diagnosis may be very difficult to make and the chief symptoms may be fever pain and loss of weight Hematuria pyuria or pain are found when the genitourinary tract is involved Localized pain and tenderness spontaneous fractures and neurologic changes due to extension into the spinal canal from vertebral lesions are the most common manifestations of bone involvement Areas of rarefaction may be demonstrable in roentgenograms although symptoms may be present long before roentgenographic signs become evident Subperiosteal infiltration may occur or the bone marrow involvement may be extensive Of cutaneous manifestations pruritus is the most frequent and this is encountered particularly in Hodgkin s disease Brownish skin pigmentation herpes zoster and nodules produced by infiltration by the specific cells are among other skin manifestations which may be encountered Symptoms and signs may also develop which are secondary to swellings producing pressure in various areas

Constitutional symptoms may appear early in Hodgkin s disease but they occur late in the other lymph node disorders Hodgkin s disease in particular may produce a great variety of manifestations so that in addition to the localized form which is much the most common a generalized type an acute type with death in a few weeks or months a "larval or abdominal form and a splenomegalic type have been described in addition to those already discussed

Fever is common in Hodgkin s disease although the well known Pel Ebstein type of fever is actually uncommon appearing no oftener than in 16 per cent of cases This form of fever consists of febrile periods of several days to several weeks duration in which the temperature remains at levels of approximately 102 to 104 F alternating with periods of weeks to even months during which there is no fever whatever

Blood Picture The greatest degree of variation is found in the blood picture associated with these disorders There may be no changes whatever On the other hand there may be profound anemia as well as striking changes in the leukocytes and platelets In Hodgkin s disease changes in the blood occur relatively early The anemia in Hodgkin s disease is usually only moderate in degree and normocytic in type very occasionally hemolytic anemia develops The total leukocyte count in Hodgkin s disease may be slightly or moderately increased it may be normal or there may be leukopenia Sometimes the leukocyte count may exceed 25 000 per cubic millimeter The differential count may show neutrophilia relative and absolute lymphocytopenia monocytosis or eosinophilia All these changes may be present at the same time or none of them Eosinophilia which is mentioned frequently as characteristic of Hodgkin s disease and which may sometimes be very pronounced is found only in about 20 per cent of cases An absolute increase in the number of lymphocytes suggests some disease other than Hodgkin s Neutropenia suggests extensive bone marrow or splenic involvement

The leukocyte picture in the other forms of disease chiefly affecting lymph nodes is more frequently normal than is the case in Hodgkin s disease Relative and even absolute lymphocytosis may be seen The lymphocytes may be of normal types but unusual forms and tumor cells" (p 1216) have been described Monocytes may be increased in number and young forms may be seen but a consistent and characteristic picture has not been described

The platelet count may be increased in Hodgkin s disease and large bizarre forms may be seen It is more common however to find the platelet count normal In some instances thrombocytopenia is present this usually occurs when leukopenia is found as well The presence of thrombocytopenia suggests extensive bone marrow or splenic involvement and is usually although not necessarily a grave sign

Bone Marrow Picture As would be expected from this description of the blood findings changes in the bone marrow are not characteristic and are seldom helpful except in rare cases of so called "bone marrow Hodgkin s in which there is extensive involvement of the bone marrow Reed Sternberg cells have been demonstrated in the bone marrow in a few cases of Hodgkin s disease Lymphocytosis may be found in the bone marrow in some cases of lymphosarcoma and of giant follicular lymphoma Such cases raise serious doubt as to whether there is any true difference between them and chronic lymphocytic leukemia

produces little or no nausea and vomiting In Hodgkin s disease 10 to 15 mg may be given in a course and maintenance doses of 5 to 10 mg per month have been employed Lymphosarcoma like chronic lymphocytic leukemia is more sensitive and 2 to 5 mg may produce an effect Other lymph node disorders may require amounts intermediate between these quantities However the potential hematopoietic depressant action limits its usefulness

Urethan Myleran and the folic acid antagonists offer little or nothing in the treatment of the lymph node disorders under discussion and the steroid hormones are only occasionally and transiently useful The effects of irradiation and various chemotherapeutic agents are compared in Table 108 (p 1219)

In addition to these measures general supportive and symptomatic therapy will be required in individual cases

Prognosis The most important factor which seems to determine the course of these disorders is their inherent character Cases of Hodgkin s disease and of lymphosarcoma are known to have run a chronic course for many years In other instances the course is rapid and progression occurs in spite of therapy In general cases with the most favorable outlook are those in which only one accessible lymph node group is affected and where evidences of systemic involvement such as fever loss of weight increased sedimentation rate and changes in the blood are lacking In the last analysis a therapeutic trial should be attempted for a prolonged remission mav sometimes be encountered even in cases in which the general examination suggests a hopeless prognosis

221 MULTIPLE MYELOMA

M M Wintrobe

Definition Multiple myeloma is characterized by the development of multiple tumors of bone which produce pain pathologic fractures and anemia There may be diffuse involvement of the bone marrow and in the urine or blood a peculiar protein is usually found Rarely a localized tumor is the only manifestation Tumors composed of other types of cells have been described but the evidence is all in favor of a single type ("myeloma" or plasma cell)

Etiology The disease appears most commonly after the age of forty and is twice as frequent in males as in females The cause is unknown The true nature of the peculiar protein is not clear It is presumed that the myeloma cell is responsible for the protein anomalies of multiple myeloma This cell has the cytochemical characteristics of an intensely protein producing cell as judged by ultraviolet microscopy Protein with ultracentrifugal and electrophoretic properties similar to those of the abnormal components present in the plasma in this disease has been extracted from myeloma tumor tissue Some investigators hold however that rather than being a neoplastic growth multiple myeloma is due to a derangement in protein metabolism

Symptoms Pain is the most frequent complaint and is produced by the tumors which according to their location may or may not be discoverable on physical examination The tumors range from the size of a pea to that of a hazelnut They are confined for the most part to the sites of the red marrow the ribs sternum spine clavicles skull or the extremities about the shoulder or pelvic girdle Roentgenograms reveal discrete punched out lesions osteoporosis and pathologic fractures Deformity and neuralgic or neurologic symptoms may develop Less frequently anemia abnormal bleeding or symptoms suggesting nephritis are the chief manifestations

Laboratory Findings Anemia is moderate in degree as a rule and normocytic but sometimes it is severe and macrocytic Enumeration of the cells may be difficult because of clumping a peculiarity often related to the great quantity of globulin in the plasma In blood smears there may be a marked tendency to rouleaux formation Polychromatophilia stippling and even normoblasts may be found in the blood smear The leukocyte count may be normal slightly increased or low Myeloma cells like those seen in the bone marrow may be found The platelet count is usually normal

Hyperproteinemia may be present (50 to 65 per cent of cases) and sometimes extremely high values are found The increase is due to the globulin fraction Sometimes the protein precipitates or coagulates spontaneously when the plasma is exposed to low temperatures (cryoglobulin) Its presence may be associated with a variety of symptoms especially those suggesting the Raynaud syndrome Detailed studies have revealed that the type of

Diagnosis The differential diagnosis of lymph node enlargement was discussed in an earlier chapter (p 224) Cases in which there is little or no enlargement of the superficial lymph nodes present the most difficult problem in diagnosis for then a variety of inflammatory and neoplastic disorders of the mediastinum lungs gastrointestinal tract or liver must be considered and the possible presence of chronic infections such as brucellosis must be ruled out Hodgkin s disease in particular may produce such varied manifestations that this disorder must be kept in mind almost whenever diagnosis is obscure This disease is particularly suggested by such symptoms as relapsing fever loss of weight and splenic or hepatic enlargement together with anemia and leukocytosis or leukopenia

Treatment Surgical excision irradiation and chemotherapy all have their place in the treatment of these disorders Surgery is useful when the condition is definitely localized irradiation is effective in the treatment of local manifestations and when the disease is generalized and chemotherapy is particularly indicated when the disorder is widespread Sometimes all three forms of therapy can be employed and frequently there are advantages in using both irradiation and chemotherapy

Since these conditions in many instances appear to arise locally and only disseminate later *surgical excision* should be an excellent form of therapy Unfortunately correct diagnosis is not often made early Furthermore in many instances in which the disease seems to be local dissemination has already occurred or has been present from the beginning Nevertheless this form of therapy when appropriately applied offers the only chance of cure Surgical excision if undertaken must be radical and should be followed by irradiation or chemotherapy or both Surgery should also be considered in the form of splenectomy when signs of hypersplenism are present severe anemia with shortened life span of transfused red corpuscles leukopenia and thrombocytopenia

Roentgen rays represent the preferred method of *irradiation* this apparently being somewhat superior to the use of radioactive phosphorus and more effective than radium Generally speaking segmental or localized irradiation is used rather than total irradiation except in cases in which generalization has taken place Various areas are treated in succession The decision as to dosage is the problem of the radiotherapist The total amount depends on the response of the lesions to therapy the general effects on the patient and the effect on the blood The effect of irradiation may be dramatic large masses melting away in the course of a week Pressure symptoms may disappear fever and pruritus if present may be relieved and pain caused by bone involvement may be alleviated Pulmonary lesions may decrease in size and pleural effusions may clear Anemia may disappear and the leukocyte count if elevated may drop to normal In other cases irradiation is less effective in some instances being of scarcely any benefit Prediction in advance as to the likelihood of benefit from therapy is often difficult In general the more chronic and slowly growing forms respond best to therapy Remission following treatment may last but a few weeks or may persist a year or longer In some cases such improvement can be reproduced many times by additional therapy

The action of *nitrogen mustard* in these disorders is similar to that of irradiation but in certain cases of Hodgkin s disease this drug seems to be more effective than irradiation It has been found that in some cases previously given roentgen therapy and no longer responding to such treatment nitrogen mustard therapy has been distinctly beneficial Other cases treated with nitrogen mustard from the beginning have responded well and in general in a manner similar to that already described under roentgen therapy Fever often disappears promptly and anemia if present also is alleviated Abnormalities in the leukocytes may revert toward normal although the immediate effect noticeable within 5 to 14 days following the first dose of nitrogen mustard may be leukopenia and an increase of anemia Thrombocytopenia if present at the initiation of therapy is less likely to be relieved by treatment

Nitrogen mustard [methyl bis(β chloroethyl) amine hydrochloride HN2] is given intravenously in doses ranging from 0 1 to 0 3 mg per kg body weight per injection each day As much as 0 8 mg per kg constitutes a course of therapy although the usual amount is 0 4 to 0 6 mg The drug is available in vials containing 10 mg In order to prevent thrombosis a solution of normal saline is first introduced intravenously and when this is flowing freely 10 ml saline solution is added to the vial where the drug dissolves readily The appropriate dose is withdrawn and injected through the rubber tubing of the saline infusion Nausea and even vomiting may follow several hours after injection of the drug but this is usually of shorter duration even though sometimes more intense than that seen in irradiation sickness The nausea and vomiting can be allayed or prevented by giving chlorpromazine in three 20 to 30 mg doses 6 and 4 hr before and at the time of the injection

The discovery of other chemotherapeutic agents has reduced the comparative importance of nitrogen mustard in the treatment of the various forms of leukemia and the lymphomas with the exception of Hodgkin s disease *Triethylenemelamine* (p 1219) appeared at first to be very promising because it has the advantage as compared with nitrogen mustard that it can be given by mouth and

cases Both these changes can be ascribed to the renal damage associated with the deposits of Bence Jones protein which are found not only in the distal tubules but in the entire nephron up to the proximal convoluted tubules The resulting distention and obstruction to renal flow lead to glomerular atrophy and ultimate renal failure (myeloma kidney") It is thus not unusual in multiple myeloma to find albumin casts and renal epithelial cells in the urine and evidence of renal functional impairment as well as nitrogen retention often develop

The *bone marrow* frequently contains the tumor cells although their number may range from 3 to 96 per cent The myeloma cell is moderately large (15 to 30 μ), and round or ovoid and contains a round eccentrically placed nucleus which may contain one or two nucleoli The chromatin is moderately coarse The cytoplasm is bright blue Attempts have been made to classify myeloma cells according to their maturity and to establish some correlation to the clinical manifestations of the disease Some tendency for patients with the more mature cell types to live longer and for those with greater percentages of immature cells to manifest renal involvement has been observed but extreme variations have been encountered in individual cases and no consistent correlation between cell type and extent of bone involvement hyperglobulinemia Bence Jones proteinuria or the electrophoretic distribution of the various globulin fractions has been established

Diagnosis The multiple bone lesions the excretion of Bence Jones protein the hyperproteinemia and the characteristic cells in the bone marrow form a combination of findings which makes the diagnosis evident Difficulty arises when back pain obscure anemia or some complaint of nonspecific character has failed to suggest this disease and the appropriate examinations have not been made Sometimes the picture may closely simulate hyperparathyroidism (see p 577)

Prognosis and Treatment The prognosis is unfavorable The average duration is 2 to 3 years Great variations occur however and some patients live for many years Local irradiation is often helpful and may be strikingly so if there is a single bone lesion The effects of irradiation on myeloma are rather unpredictable however Urethan is perhaps the best therapeutic agent currently available but even its value is limited Although subjective improvement is associated with its administration in about half the cases objective improvement has been observed in only about 20 per cent To achieve any benefit doses of 2 to 5 Gm daily have to be given for periods of 6 to 10 weeks With these doses nausea and vomiting may develop and may necessitate withholding the drug Other chemotherapeutic agent including stilbamidine nitrogen mustard and triethylene melamine are of even less value The effects of the steroid hormones have been disappointing

222 OTHER DYSPROTEINEMIAS AND PARAPROTEINEMIAS

M M Wintrobe

History Definitions and Clinical Syndromes Although multiple myeloma and Bence Jones proteinuria were recognized in 1845 the presence of a cold precipitable protein in the serum of a patient with this disease (*cryoglobulin*) was not described until almost a century later (Wintrobe and Buell 1933) *Macroglobulins* high molecular weight proteins demonstrable only by ultracentrifugation and a syndrome associated with *macroglobulinemia* were described in 1944 (Waldenstrom) Since that time with the exploitation of electrophoretic ultracentrifuge and serologic techniques considerable attention has been attracted to the occurrence of aberrations in protein metabolism in association with various diseases and sometimes in the absence of any associated disorder In some instances it appears that the unusual findings represent only increases of normally occurring protein molecules (*dysprote*

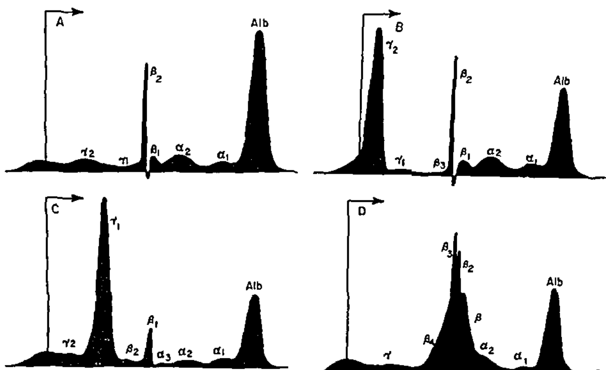

FIG 158 Descending patterns after 250 min of pooled normal serum (A) and serum from two patients with multiple myeloma (B and D) and one patient with macroglobulinemia (C) determined by electrophoretic analysis at 1 C in 0 1 ionic strength Veronal buffer at pH 8 4 to 8 5 Note the large gamma globulin component (γ) in (B) and the beta globulins in (D) as well as the gamma globulin (γ_1) in the case of macroglobulinemia (C) The very narrow β peaks in (A) and (B) are anomalies probably due to lipoproteins and are not unusual in serums from nonfasting subjects (*Courtesy Drs Emil L Smith and B V Jager and Mr Douglas M Brown*)

protein which is predominant differs from one case to another In the majority of cases gamma globulin is increased in others it is beta globulin and in the minority the substance is an alpha globulin The diagnostic patterns in multiple myeloma as measured by the Tiselius electrophoretic technique are characterized by tall narrow sharply defined peaks owing to the presence of large amounts of a relatively homogenous abnormal protein (Fig 158 *B* and *D*)

When the *urine* is heated a white cloudy precipitate appears at temperatures of 50 to 60 C but when the temperature is raised to near the boiling point the precipitate redissolves Such Bence Jones protein has been observed in 40 to 50 per cent of cases As judged by various physicochemical determinations Bence Jones proteins are related neither to normal serum proteins nor to the abnormal serum proteins As judged by serologic reactions however they appear to be related to normal serum proteins Bence Jones protein can be synthesized readily from free amino acids rather than from tissue protein precursors There is evidence that myeloma serum globulins may be conjugated glycoproteins containing a significant quantity of carbohydrate bound to the protein component In contrast the urine myeloma proteins seem to be devoid of any significant carbohydrate component

In addition to the hyperproteinemia and the Bence Jones proteinuria a third form of protein abnormality may be observed in multiple myeloma This is the deposition of a peculiar protein in the tissues producing atypical amyloidosis or *paramyeloidosis* This has been observed upon histologic examination in 6 to 10 per cent of cases of multiple myeloma

Not infrequently certain chemical changes are found in the blood *Hypercalcemia* has been observed in 20 to 53 per cent of cases values of 12 to 16 mg per 100 ml being not unusual With progression of the disease the hypercalcemia may increase The high serum calcium levels have been attributed to the resorption of bone which takes place but they are further increased by secondary hyperplasia of the parathyroids caused by renal impairment As a rule the hypercalcemia is not accompanied by a decrease in the inorganic serum phosphorus or by much increase in alkaline phosphatase thus differing from the changes found in primary hyperparathyroidism

The serum uric acid is not infrequently increased and nitrogen retention has been noted in many

Plasma cells are thought to be the source of cryoglobulins and atypical lymphocytic cells the source of macroglobulins but more primitive or more malignant precursors of these cell types are also thought to produce these unusual plasma proteins

Diagnosis Hyperproteinemia is found in most cases and is generally attributable to a great increase of globulin usually gamma globulin In most instances the globulin fraction amounts to 4 to 8 Gm per cent The Sia test which involves mixture of the patient s blood with distilled water and observation of the formation of a precipitate when positive has not been found to be a reliable screening test for macroglobulinemia The electrophoretic pattern of severe macroglobulinemia is indistinguishable from that of multiple myeloma Immunologic diagnosis with antimacroglobulin serum has been successful in most cases studied but ultracentrifugation should be carried out in suspected cases since it yields the critical evidence

The diagnosis of cryoglobulinemia offers no particular difficulty but since cryoglobulins have a wide thermal amplitude blood for these studies should be drawn into warm syringes and separation of serum or plasma carried out at 37 C Cold precipitation reversible on warming is characteristic The differential diagnosis of cryoglobulinemia should include consideration of cryofibrinogens and cold agglutinins

Macroglobulinemia should be distinguished from *purpura hyperglobulinemica* characterized by dependent purpura and hypergammaglobulinemia The characteristic electrophoretic gamma globulin peak in this syndrome is a broad hump in contrast to the sharp peak of macroglobulinemia

Prognosis and Treatment The prognosis in the secondary forms depends upon the nature of the underlying disease process The primary disorders are compatible with survival for several years If death occurs it is usually due to severe anemia complicating infections or the hemorrhagic diathesis ACTH or adrenocorticosteroid therapy has sometimes seemed to be helpful

Section 2 The Cardiovascular System

A DISEASES OF THE HEART

T R Harrison and
William H Resnik

Of the various disorders which afflict mankind those of the heart and blood vessels assume first rank In the United States these disorders represent the single greatest cause of chronic disability and are responsible for more deaths than the next five most common causes combined As other diseases are conquered by the progress of medical science the proportion of persons living to the advanced ages at which cardiovascular diseases are most common continually increases Barring the possibility of as yet unforeseen discoveries leading to more effective prevention and treatment of these disorders it can be estimated that one third or more of the present population of the United States will die of cardiovascular disease Among males engaged in business and professions the proportion will perhaps be nearer one half

Present knowledge of cardiovascular disease rests upon the solid foundation of clinical physiology Among those who have contributed most to understanding of these disorders are William Harvey who first demonstrated clearly the circulation of the blood after this concept had been suggested by Cesalpino William Withering who introduced the

inemias) whereas other studies suggest that they denote aberrant protein synthesis (*paraproteinemia*)

Cryoglobulinemia of minor degree (less than 25 mg per cent) may be encountered in a large variety of disorders including systemic lupus erythematosus rheumatoid arthritis periarteritis nodosa chronic lymphocytic leukemia lymphosarcoma polycythemia rubra vera kala azar subacute bacterial endocarditis coronary artery disease hepatic cirrhosis and numerous other diseases Rarely the cold precipitable protein is present in large amounts and is associated with atypical Raynaud phenomena purpura bleeding from nose and mouth retinal hemorrhages cold sensitivity cyanosis mottling and even gangrene of the lower extremities Multiple arterial and venous occlusions may occur Rouleaux formation pseudoagglutination of the red cells and an elevated erythrocyte sedimentation rate are likely to be found as well In most instances of this sort multiple myeloma has been demonstrated and rarely other disorders such as chronic lymphocytic leukemia In a few instances no underlying disease entity could be demonstrated (*essential cryoglobulinemia*)

The concentration of cryoglobulin in plasma or serum has ranged from trace amounts to 10 Gm per cent The amount may vary over the course of the illness in the same patient The minimum concentration of cryoproteins required for massive reversible precipitation is about 1 Gm per cent The precipitation of the plasma protein is due to its decreased solubility in the blood and can be demonstrated in vitro The most commonly occurring cryoglobulins have been found in the gamma fraction but globulins in the alpha fraction in the beta fraction and between the beta and gamma peaks have also shown this property Molecular weights have ranged from 165 000 to 600 000

Macroglobulinemia is detectable with certainty only by ultracentrifugal analysis The molecular weight of the macroglobulins is greater than 1 million Trace amounts of macroglobulins are present in normal serums The term *macroglobulinemia* is applied to serums containing more than 5 to 10 per cent of components sedimenting with a Svedberg constant greater than 15 Pathologic macroglobulin molecules have the electrophoretic mobility of beta or gamma globulins or are intermediate between these two Occasionally an abnormal plasma protein may be both a cryoglobulin and a macroglobulin

Macroglobulinemia has been observed in the nephrotic syndrome in cirrhosis in association with malignant tumors and in congenital syphilis Serums of multiple myeloma have seldom been reported to show abnormal high molecular weight components In the syndrome described by Waldenstrom *primary macroglobulinemia* in contrast to multiple myeloma focal bone lesions are not found there being at most a diffuse osteoporosis but slight to moderate lymphadenopathy and hepatosplenomegaly are characteristically encountered Bone pain is conspicuously absent In clinical features primary macroglobulinemia thus resembles lymphosarcoma rather than multiple myeloma Symptoms and signs of vague ill health some weight loss lassitude dyspnea and recurrent infections are common as well as pallor and edema Sjogren s syndrome (dryness of mucous membranes in eye nose mouth and vagina) has been described in association with macroglobulinemia Epistaxis and mucosal bleeding are frequent Anemia usually normocytic is present leukopenia relative lymphocytosis sometimes eosinophilia or monocytosis as well as thrombocytopenia hemolytic anemia and *pancytopenia have been observed Bence Jones* proteinuria and paramyloidosis such as are seen in multiple myeloma have been reported The bone marrow characteristically shows large numbers (40 to 80 per cent) of small atypical "lymphocytic" cells with protoplasmic shedding and "naked nuclei" The erythrocyte sedimentation rate is markedly elevated Bleeding time coagulation time and prothrombin time may be prolonged and prothrombin consumption may be impaired

Pathology and Pathogenesis In the secondary forms of dysproteinemia and paraproteinemia the pathologic findings are those of the underlying disorder In the primary disorders no specific changes have been noted except for the signs of *reticuloendothelial hyperplasia and the bone marrow* and lymph node infiltration with small atypical lymphocytes which have been observed in primary macroglobulinemia When cryoglobulinemia has been present pulmonary arteriolar obstruction has been described as well as vascular occlusion elsewhere (kidneys etc) Symptoms associated with cryoglobulinemia have been attributed to precipitation of cryoprotein in peripheral blood vessels as well as to cold agglutination of red cells by this protein in vivo The bleeding tendency has been attributed to intravascular precipitations with secondary capillary damage and in some cases to defects in platelet function

No uniformity in the physicochemical characteristics of macroglobulins has been demonstrated Macroglobulin peaks in the electrophoretic diagram are sharp and cannot be differentiated from myeloma proteins (Fig 158C) Macroglobulins frequently sediment in the ultracentrifuge as multiple components Studies of their amino acid composition have *shown variations from patient to patient It* is uncertain from immunologic studies whether the macroglobulins and cryoglobulins represent increases of normally occurring protein molecules or denote aberrant protein synthesis

there is strong evidence that anxiety worry and emotional stress not only make the patient unhappy but may actually tend to aggravate the structural disorder and hence one of the prime principles in management is to attempt to remove all sources of psychic stress whether they be related to anxiety about the heart or to environmental factors concerning family business etc In the patient with cardiac as with most other chronic diseases there are many situations in which the physician himself becomes the treatment and in which happiness depends mainly and health partly on the physician s wisdom optimism tact and perhaps above all else on his willingness to devote as much time as may be required to listening to the patient s troubles and to alleviating his anxiety

Treatment of Underlying Disease Process Certain causes of cardiac disease unfortunately not the most common ones are amenable to cure Hence one of the primary therapeutic principles is to search constantly for such cases In the majority of instances these curable conditions are those associated with the clinical manifestations of high output failure (p 101) i e the signs of congestive failure occurring in association with the signs of the overactive heart When as in the great majority of patients with congestive failure such manifestations are absent one should think first of all of mitral stenosis or aortic stenosis then of constrictive pericarditis and of myxedema as possible causes In an individual with congenital heart disease the first thoughts should concern patent ductus arteriosus coarctation of the aorta pulmonic stenosis interauricular septal defect and the tetralogy of Fallot because these conditions likewise are completely or partially curable

Physical Activity A sharp distinction must be made between those patients presenting evidence of recent myocardial injury and those in whom no such evidence exists Patients with acute rheumatic carditis should be kept at complete rest and allowed out of bed only for purposes of bowel movement Patients with subacute rheumatic carditis represent a special problem After myocardiac infarction rest is indicated with the realization that prolonged bed rest carries serious hazards (p 1267)

In the absence of evidence of recent or progressive myocardial injury the problem of physical activity is different It is here that overzealous insistence by the physician on unnecessary restrictions so often creates a state of anxiety and psychic invalidism which is more disabling to the patient than the underlying structural disease In the absence of acute or recent myocardial injury there is no evidence that physical activity which can be tolerated by the patient without symptoms is harmful Hence the rule of living for such patients is a simple one and consists of living below the symptom threshold In other words *the patient should not do anything which induces pain of the anginal type or dyspnea but may carry on physical exertion which does not cause these symptoms This principle of management is probably the single most important feature of the treatment of chronic cardiac disease* for adherence to it will automatically adjust the patient s activities to things which can be done without overburdening the heart and at the same time allow all the leeway which the cardiac condition permits Moreover it will tend to prevent the development of that anxiety state which is so commonly the most important feature of the disease as far as the happiness of the patient and of his family is concerned For the appropriate patient the knowledge that he is permitted to participate in a game of golf or some other moderate form of physical exertion has a greater psychotherapeutic value than verbal assurances that have no concrete meaning to him

223 DIAGNOSTIC ASPECTS OF HEART DISEASE (Including Treatment of the Arrhythmias)

T R Harrison and William H Resnik

It should be emphasized at the outset that persons either do or do not have heart disease and that while the decision is at times difficult and rarely may be impossible there is no intermediate state Hence such terms as a heart condition a tired heart and myocardial damage which are ordinarily used to conceal the physician s uncertainty have no place in modern medicine They should be relegated to limbo along with anginoid "pseudo angina etc

Chronic cardiac disease is of two general types one characterized by pain and the tendency toward sudden death the other by dyspnea and the tendency toward congestive failure In the diagnosis of angina pectoris the commonest variety of the first type the information obtained from the history is all important as has been stressed in Chap 4

If one omits from consideration those types of cardiac disease related to disturbance of the coronary circulation and characterized by pain as the outstanding manifestation it may be stated as a general rule that the recognition of *heart disease* depends on the objective information obtained by examining the heart while the recognition of *heart failure* depends either on subjective information

use of digitalis into medical practice René Theophile Hyacinth Laennec who introduced auscultation a method so beautifully expounded in heart disease by Pierre Carl E Potain William Heberden who described angina pectoris James Hope who described the mechanism of congestive heart failure Richard Bright who first clarified the hypertensive and renal disorders Sir James Mackenzie who was the first to emphasize that the test of a heart is its response to effort Ernest Starling who established the physiologic basis of heart failure Willem Einthoven who devised the electrocardiograph James Herrick who developed the modern clinical concept of myocardial infarction Sir Thomas Lewis who exemplified the importance of critical investigation in the study of patients with cardiovascular disorders Frank N Wilson who began the clarification of the basic principles of the electrocardiogram and Myron Prinzmetal who has resolved the previous conflicts between clinical judgment and electrocardiographic interpretation These men and many who cannot be cited here were the trail blazers while the roads have been built by the innumerable contributions of others

The physician who is confronted with a patient presenting evidence of the possible presence of disease of the heart necessarily asks himself certain questions of which the most important are

1 Is heart disease present?
2 If so what type of heart disease is it?
3 How serious is it?
4 What should be done about it?

In the sections to follow an attempt will be made to consider these questions and accordingly the diagnostic etiologic prognostic and therapeutic aspects of cardiac disease will be discussed in respective sequence Since the subjects of arteriosclerosis hypertension and rheumatic fever the most common and important causes of cardiovascular disease have been considered in other chapters the discussion to follow will deal only with such aspects of these topics as are especially pertinent No attempt will be made to consider all the less common causes of cardiovascular disease and the discussion of etiology will be centered on those factors which are especially important either because of frequency or because of susceptibility to cure

The arrangement of this section on Diseases of the Heart departs from that traditionally given in discussions of the various types of cardiac disorder To avoid needless repetition of symptoms signs criteria of prognosis and methods of treatment that are common to *many forms of heart disease regard*less of etiology discussion has been arranged primarily according to the general topics of diagnosis etiology etc The fundamental principles of diagnosis prognosis and treatment are in the main similar irrespective of the basic causes of heart disease To achieve this simplicity of arrangement and avoidance of unnecessary reiteration by rigid adherence to such a program is to introduce certain disadvantages Thus angina pectoris would require separate discussions under Pain in the Chest Etiology and Treatment the arrhythmias would need consideration under Diagnosis and Treatment etc The authors believe that a strict pursuit of this plan contains inherent disadvantages that tend to nullify whatever logic resides in such an approach to heart disease Hence an attempt has been made to resolve this dilemma of presentation by combining the various aspects of congestive heart failure into a single chapter The treatment of the manifestations of heart disease other than congestive failure are taken up in those chapters where they seem naturally to fall Thus the symptoms diagnosis and treatment of the arrythmias are considered together under Diagnostic Aspects of Heart Disease (Chap 223) the special problems of symptomatology and treatment of other conditions in the respective discussions under Etiologic Aspects of Heart Disease (Chap 224) Because of the unique problems presented by congenital heart disease a special chapter is devoted to this subject

The reader may find it useful when the commoner symptoms of heart disease are mentioned to refer to previous chapters on Pain in the Chest (Chap 4) Dyspnea (Chap 10) Palpitation (Chap 13) Edema (Chap 20) Cyanosis (Chap 12) Circulatory Failure (Chap 14) etc

PRINCIPLES OF THERAPY IN PATIENTS WITH CHRONIC CARDIAC DISEASE

Psychologic Management This is of the utmost importance When grave anxiety concerning the heart exists in the absence of structural disease thorough examination coupled with tactful and time consuming reassurance plus the use of specialized psychiatric therapy when needed will usually yield strikingly gratifying results The problem becomes more difficult when as is so often the case the anxiety state occurs in a patient presenting clear evidence of a structural cardiac disorder Here again psychic invalidism can usually be avoided if the physician will refrain from frightening the patient and will take sufficient time to discuss the problem and to explain the significance of various findings Further discussion of psychologic management will be found in Chaps 13 and 41 which deal with palpitation and anxiety respectively

It is especially important that unnecessary restrictions not be imposed on patients for there is no *evidence that physical activity which does not* induce pain or dyspnea is harmful to the person with chronic cardiac disease On the other hand

Dilatation The mechanisms of cardiac dilatation have already been discussed (Chap 14) and here it need only be repeated that dilatation results from defective systolic emptying

The x ray is of the greatest value in the decision as to the presence or absence of dilatation of the several cardiac chambers Space does not permit a detailed discussion of this important subject and the reader is referred to books on radiology Briefly it may be said that dilatation of the left ventricle tends to produce some rounding of the apex as seen in the frontal projection and backward enlargement of the cardiac shadow as observed in the left anterior oblique position Dilatation of the left auricle produces a convexity of the left portion of the cardiovascular shadow in the region between the pulmonary artery shadow and the ventricular shadow but a more characteristic sign is the bulging backward of the lower posterior cardiac shadow into the retrocardiac space with displacement or compression of the barium filled esophagus when the patient is viewed in the right anterior oblique or in the left lateral position This phenomenon is characteristically seen in some patients with mitral stenosis and/or insufficiency Right ventricular enlargement tends to cause the heart to assume a more anterior position but it is often not detected by the x ray Right auricular enlargement is usually characterized by increased size to the right

The electrocardiogram is usually of little help in the diagnosis of cardiac dilatation However the occurrence of intraventricular conduction defects with widening, slurring and notching of the QRS complexes often superimposed on the signs of ventricular hypertrophy may occur This is often striking if acute dilatation occurs suddenly with overstretching of the conduction system and of the myocardial fibers The sudden appearance of records resembling right bundle branch block often lasting for a few hours only in patients with chest pain may signal the presence of a large pulmonary embolus with transient right ventricular dilatation (acute cor pulmonale) The tall spiked P waves in leads II and III in patients with chronic lung disease (pulmonary P waves) are apparently associated with auricular dilatation and displacement since they often regress with treatment of the congestive failure

Physical examination usually yields significant and often decisive information on the important question as to whether the heart—regarded as a whole—is enlarged or not Here palpation assumes the position of first importance Whether the heart is enlarged to the left can usually be determined by palpation of the point of maximal impulse Unfortunately the position of the right border cannot be determined with corresponding accuracy by clinical method for percussion possesses limited value in the examination of the heart and does not afford an accurate guide as to the position of the right border in the majority of patients However if the point of maximal impulse is outside the mid clavicular line one can be reasonably certain that the heart is either enlarged or displaced Displacement usually to the left may result from lateral curvature of the spine More commonly it is due to disorders of the pleural cavity such as hydrothorax pleural effusion or pneumothorax all of which tend to displace the heart toward the opposite side or to atelectasis and pleural thickening which tend to displace the heart toward the affected side Hence in the absence of lateral curvature of the thoracic spine cardiac displacement can usually be recognized by examining the lungs By combining careful physical examination of the lungs with accurate palpation of the heart cardiac enlargement can be established by clinical methods alone However this decision is accurate only when the apical impulse can be felt When because of age obesity or emphysema palpation of the apical impulse is impossible the x ray must be used to determine cardiac size It is a relatively inaccurate method for this purpose The most commonly used roentgenographic index of cardiac size is the transverse diameter in relation to the total diameter of the chest This method while valuable when marked alterations in cardiac size exist is of limited value in the detection of the earlier stages of enlargement and for this purpose other more complicated methods of measurement are considered to be more accurate These too have their limitations A large apical fat pad may lead to a false x ray diagnosis of cardiac enlargement

Aside from its value in affording information concerning the size of the heart the x ray is even more useful in revealing alterations in cardiac shape which by offering an indication as to the chambers and vessels particularly affected often furnish diagnostic clues which cannot be obtained by any other means

ALTERATIONS IN HEART SOUNDS

Ventricular Volume Curve in Relation to Heart Sounds In interpreting the sounds arrhythmias and murmurs observed on auscultating the heart it is helpful to relate these phenomena to the ventricular volume curve This curve is illustrated in Fig 159 and a few of the aspects in which it may be useful are indicated in the accompanying legend

The chief factors which influence the intensity of the first sound are (1) the position of the valves at the onset of ventricular systole which is usually determined by the length of time elapsing between atrial and ventricular contraction (2) the rate of

obtained from the story or objective phenomena to be found by examining the body as a whole rather than the heart Since the present chapter is concerned with the diagnosis of heart disease rather than that of heart failure (which will be considered in a succeeding chapter) the discussion to follow will center around the recognition of those objective findings which afford either suggestive or unequivocal evidence of the presence of structural cardiac change

ENLARGEMENT OF THE HEART

This is the most common objective manifestation of cardiac disease Enlargement is of two types—hypertrophy and dilatation These commonly occur together and are related intimately to each other However since they produce *somewhat different* physical signs and have somewhat different significance they will be considered separately

Hypertrophy Much has yet to be learned about the exact mechanism responsible for an increase in the cardiac muscle mass In most cases there is clear evidence that hypertrophy of the individual muscle fiber is related to increase in work brought about either as the result of an increased load on the particular chamber concerned or as the result of disease of some fibers which become less able to carry their portion of the load and hence cause the remaining fibers to have an additional burden

The bedside recognition of cardiac hypertrophy is not difficult in young slender individuals but may be impossible in older patients with emphysema or obesity In many instances simple palpation is a more delicate guide to hypertrophy than is the electrocardiogram or the x ray Since the left ventricle makes up only a slight portion (in the region of the apex) of the projection of the heart onto the anterior chest wall hypertrophy of this chamber does not give rise to a diffuse impulse *In patients with left ventricular hypertrophy the impulse is therefore sharply localized powerful thrusting and heaving* In some patients this impulse can be recognized only when the subject is lying on his left side

Other causes of an unusually powerful apical impulse are extreme right ventricular hypertrophy and an apical aneurysm due to myocardial infarction Some patients display a bulge of the apex during anginal attacks with disappearance of the bulge as the pain and presumably the apical ischemia disappear

On the other hand when the right ventricle is hypertrophied the impulse is diffuse pulsations are observed over the entire precordial area and on palpation the beat is found to be well sustained This greater duration and heaving quality of the precordial pulsations serves to differentiate right ventricular hypertrophy from the overactive heart This condition also produces increased precordial pulsations which however are poorly sustained and of tapping quality In many instances of right ventricular hypertrophy the most striking pulsation is an oblique forward and footward thrust in the left xiphochondral notch This is particularly true when as in patients with emphysema the precordial movements are dampened by the lungs

Aside from right ventricular hypertrophy and the conditions which increase cardiac output there are other states which may cause an increase in pulsations in the left parasternal region A pronounced systolic lift is sometimes observed in patients with infarction of the interventricular septum Rarely a patient with left ventricular hypertrophy only may display such an impulse which is possibly *due to forward displacement of the septum during* systole The forceful onset and abrupt cessation of filling in patients with constrictive pericarditis may produce a *diastolic* lift of the precordium which must be distinguished from the systolic heave caused by hypertrophy of the right ventricle

Since ventricular hypertrophy frequently occurs in response to an increase in peripheral resistance the closing sounds over the semilunar valves heard over the base of the heart are increased in intensity A loud second pulmonic sound may indicate pulmonary hypertension and therefore usually right ventricular hypertrophy a loud second aortic sound suggests systemic arterial hypertension and left ventricular hypertrophy This rule does not apply of course if valvular stenosis (aortic or pulmonary) is present

When the cardiac impulse is not readily visible or palpable because of obesity or emphysema the less reliable methods must be employed The electrocardiogram may give useful information as to which ventricle is hypertrophied provided one bears in mind that confusing alterations of the form of the electrocardiogram are brought about by changes in the position of the heart (Chap 52) and by such extracardiac factors as emphysema and edema of the chest wall

Auricular hypertrophy is not detectable by physical examination and can only be suspected by fluoroscopy Broad and split P waves in bipolar electrocardiographic leads (usually associated with biphasic P waves in right sided chest leads) may be the only direct guide to left auricular hypertrophy (mitral P waves) Right auricular enlargement may be associated with tall narrow P waves

The x ray may at times yield useful information concerning hypertrophy of the various chambers but it is more apt to be valuable when dilatation coexists In many instances of right ventricular hypertrophy the x ray and the electrocardiogram reveal what appears to be a normal sized heart

the atrioventricular valves This is presumed to occur in impending or existent ventricular failure because under these circumstances the auriculo-*ventricular pressure gradient* is higher than normal at the onset of ventricular filling and the sudden equalization of pressure produces the changes in tension of the cusps When this occurs in early ventricular filling shortly after the atrioventricular valves *open* a *protodiastolic* gallop is produced when this occurs late in diastole as a result of auricular contraction a presystolic gallop ensues According to a second view the sound is not valvular in origin but is due rather to the impact of the increased early or late ventricular filling wave against the chest wall The adherents of this hypothesis believe that alterations in the ventricular wall as a result of failure permit the transmission of the impact of ventricular filling wave through the ventricles to contiguous structures A third view ascribes the gallop sound to sudden tensing of the pericardium as the dilated heart fills

The gallop is an important phenomenon because *it indicates* that the heart is dilated and that heart failure *if not present* is imminent The peculiar significance of the gallop is therefore that *this is the only physical sign to be elicited on examining* the heart which signifies that heart failure is either present or likely to occur All the other manifestations of heart failure tend to be elicited on examining other parts of the body

Aside from isolated presystolic and protodiastolic gallops one may have a summation gallop which occurs when the heart is dilated and the rate is rapid and since atrial contraction takes place very soon after the early rapid filling phase of diastole the two sounds are superimposed

Other types of three sound rhythm are less common and although in a given patient the recognition of the type may be of great practical importance space does not permit a detailed discussion The more salient points of the three sound rhythms are summarized in Table 109

HEART MURMURS

The rapid advances in cardiac surgery have made the precise recognition of the type and severity of valvular lesions a matter of practical rather than academic significance The several valvular lesions are considered in the next chapter and the discussion here deals only with certain general principles in regard to the interpretation of murmurs

When a heart murmur is heard one wishes first to know whether it is of functional origin and completely innocent or due to a structural lesion of the heart For practical purposes all diastolic murmurs are to be considered of structural origin This applies even to those faint early diastolic blows which are heard only along the left sternal margin during forced expiration with the patient leaning forward and to those short apical rumbles heard only after exercise in the limited region of the apex thrust with the patient lying on the left side Even when the usual causes aortic insufficiency and mitral stenosis are absent the diastolic murmurs still indicate organic disease of the heart. Some of the features which may aid in the detection of the less common causes of diastolic murmurs are summarized in Tables 110 and 111

The problem of the systolic murmur is more complex When such a murmur is loud (grade IV or more) or when it replaces the first sound at the apex or when it is associated with a genuine purring thrill it is of structural origin Even when these features are absent an apical systolic murmur should be considered significant if there is a diastolic murmur also or an opening snap The presence of a rheumatic history or of a very loud high pitched first sound makes it probable that an apical systolic murmur indicates mitral insufficiency Coexisting cardiac enlargement indicates that an apical systolic murmur is due to disease of the valve cusps to fibrosis of the annulus or to dilatation of the valve ring (relative mitral insufficiency)

At the aortic area faint systolic murmurs are common in patients with hypertension or dilatation of the aorta or syphilitic aortitis Even when such faint murmurs are transmitted to the carotid arteries they should not be considered as indicative of aortic stenosis unless accompanied by some of the other cardinal findings of this lesion Of these findings the faint or absent aortic second sound is the commonest while the thrill and the fluoroscopic demonstration of calcification of the aortic cusps are the most significant The plateau pulse is observed only when the lesion is far advanced When the systolic murmur is rough and loud at the aortic area these confirmatory signs are rarely needed However they are of importance when as occasionally happens the murmur is loudest at the left sternal margin or even at the apex.

Faint systolic murmurs at the pulmonary area are usually of functional origin and are especially common in individuals with anxiety states or with disorders accompanied by increased cardiac output Loud systolic murmurs along the left sternal margin are likely to indicate congenital malformation and especially an interventricular or interauricular shunt or pulmonic stenosis When the murmur at the pulmonary area is of moderate (grade III) intensity all these several possibilities must be considered and occasionally the differentiation of functional from congenital murmurs can be achieved only by cardiac catheterization Mitral stenosis and the other disorders which cause pulmonary hypertension (Chap 224) are also common causes of

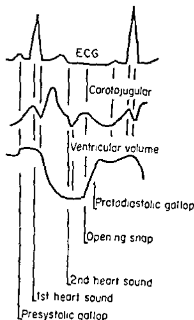

FIG 159 The *carotojugular* tracing represents the venous pulse during diastole with the characteristic waves During ejection the curve is of the arterial type The *ventricular volume* curve displays a small upstroke shortly after the onset of the P wave of the ECG The *presystolic gallop* occurs at this time During isometric contraction and isometric relaxation the ventricular volume curve is flat because blood is neither entering nor leaving the ventricle all valves being closed At the onset of the descent of the jugular V wave there is a sharp upstroke in the ventricular volume curve indicating rapid filling The opening snap of mitral stenosis occurs as ventricular filling begins The *protodiastolic gallop* occurs later toward the end of rapid filling

rise of ventricular pressure (3) the presence or absence of structural disease of the mitral valve and (4) the amount of tissue between the heart and the surface Loudness of the first sound is favored by short conduction time high cardiac output mitral stenosis and thinness the reverse of these conditions tends to be associated with faintness of the first sound

Aside from such extracardiac factors as obesity emphysema and effusions in the chest the intensity *and to some extent the quality of the second heart* sound may be influenced by alterations in the character of the vessel walls Accentuation of the aortic second sound is a normal phenomenon with age and occurs in such conditions as arteriosclerosis or syphilitic aortitis which may cause diffuse change in the physical properties of the wall of the aorta The other conditions which affect the intensity of the second sound are primarily those which alter the pressures in the aorta and pulmonary artery an increase in pressure tending to be associated with accentuation of the corresponding sounds

Three-sound Rhythms Under many different circumstances one hears upon listening to the heart not two sounds but three and the proper interpretation of the mechanisms and the significance of the extra sound will often prove to be of value in diagnosis The most common cause of a three sound rhythm in young persons is the presence of a normal third heart sound Here the additional sound is related to a change in tension in the auriculoventricular cusps as filling occurs

Almost equally as frequent as the physiologic third heart sound and of much greater practical significance is the gallop rhythm This term should be limited to a description of an extra sound occurring in diastole producing a cadence of sounds resembling that of a galloping horse (Fig 160) The protodiastolic gallop of a single cardiac cycle resembles the sequence when a physiologic third sound is present but the impression conveyed to the ear is quite different because the gallop usually occurs only in the presence of moderate to marked tachycardia and is not ordinarily observed with slow heart rates

Most gallops appear to arise in the left side of the heart as they are loudest during expiration and at the apex When a gallop is best heard during inspiration in the left parasternal region it is likely to be of right ventricular origin

The mechanism of the gallop rhythm is still a matter of dispute According to one view the sound is valvular in origin and is due to a wave of ventricular filling which causes a sudden tensing of

FIG 160 Presystolic and protodiastolic gallops After the P wave and shortly before the QRS begins a sound is noted This is the presystolic gallop and is related to ventricular filling induced by auricular contraction Approximately 0 12 sec after the beginning of the second heart sound there is an additional extra sound This is the protodiastolic gallop and occurs soon after auriculoventricular valves open and as the early rapid filling occurs

The gallop rhythms are so designated because the sound conveyed to the ear resembles that of a galloping horse

The gallop sounds are rarely heard except in the presence of tachycardia A three sound rhythm resembling during a single cycle the protodiastolic gallop is heard in young individuals with normal slow hearts This is the physiologic third heart sound However the cadence is not that of a gallop because the characteristic tachycardia is usually absent in such normal *persons*

Table 110 DIFFERENTIAL DIAGNOSIS OF THE MORE IMPORTANT CAUSES OF BASAL DIASTOLIC MURMURS

Origin and cause of murmur	Important points in history	Usual age of patient	Special features of murmur	Cardiac enlargement	Peripheral vascular signs	Important associated findings	Remarks
Rheumatic aortic regurgitation	Rheumatic fever	10–40	Early diastolic blowing Faint or loud	Left ventricular type	Regurgitation or stenosis	Mitral stenosis auricular fibrillation	Signs frequently modified by coexisting aortic stenosis and mitral lesions
Syphilitic aortic regurgitation	Syphilis	35–60	Blowing early diastolic often loud	Left ventricular type	Regurgitation	Positive serologic tests in about 85 per cent	Especially middle-aged Negro males aorta usually dilated (x-ray) Confusing systolic murmurs common
Hypertension		40+	Very faint	Left ventricular type	Absent	Hypertension (diastolic)	Regurgitation slight
Calcific aortic disease	Syncope Angina pectoris	55+	Diastolic faint systolic loud with systolic thrill	Left ventricular type	Stenosis	Calcification of aorta and aortic valves (x-ray)	Signs of stenosis predominate
Bacterial endocarditis	Rheumatic fever or murmur at birth	Any	Often intermittent	Left ventricular type	Regurgitation or stenosis	Fever positive blood culture Emboli Petechiae Hematuria	Usually superimposed on rheumatic lesion rarely on syphilitic or congenital bicuspid aortic valve
Bicuspid aortic valve		10–40	Faint			Liable to bacterial endocarditis	Usually associated with coarctation of aorta
Dissecting aneurysm	Sudden violent pain	35+	Often intermittent	Non left ventricular	Asymmetry in blood pressure	Hypertension	Cardiac tamponade from rupture into pericardium
Pulmonic regurgitation: Graham Steell murmur	Rheumatic fever or cor pulmonale	10–40	Faint, early blowing	Right ventricular type	Pulmonic second increased	Mitral stenosis or cor pulmonale	Impossible to distinguish from minimal aortic regurgitation
Pulmonic regurgitation: Overacting heart	Palpitation	Any	Faint early blowing		Bounding pulse	Anemia hyperthyroidism	Diastolic murmurs rare and faint systolic common and loud
Pulmonic regurgitation: Congenital lesions	See discussions of patent ductus arteriosus Eisenmenger complex, and Lutembacher syndrome						

occasional instance of asymptomatic minimal mitral insufficiency than to induce unnecessary alarm and anxiety

The Late Systolic Murmur Elderly persons may display faint or moderate murmurs which are loudest in the region of the apex, are often somewhat harsh begin in midsystole and last until the second heart sound. They may have a crescendo quality and this may lead to an erroneous diagnosis of mitral stenosis These late systolic murmurs are unique in that they are separated from the first sound by a distinct pause

The mechanism of these murmurs is unknown Some of the patients present evidence of cardiac failure without obvious cause and hence are considered to have senile heart disease (presbycardia) Others display the characteristic anginal pain of coronary disease or electrocardiographic changes pointing toward a previous myocardial infarction Necropsy has revealed fibrosis of the mitral annulus in some instances but in others has failed to furnish an adequate explanation for the murmur Auriculoventricular block of the higher grades is not infrequent in elderly patients with such murmurs

In younger persons these late systolic murmurs are rare They appear to be of extracardiac origin in some individuals and due to rheumatic disease of the mitral valve in others

Heart murmurs in patients with congenital heart disease are discussed in Chap 225

Thrills In the region of the apex thrills are of limited diagnostic import because they may be confused with vibrations set up by a vigorously beating heart On the other hand the presence of a thrill at the base of the heart or along the left sternal border constitutes practically *conclusive evi*

Table 109 DIFFERENTIAL DIAGNOSIS OF THE MORE COMMON CAUSES OF THREE SOUND RHYTHMS AT THE APEX *

Condition	Time of cardiac cycle	Third sound ventricular volume curve	Associated conditions	Significance of sound	Probable mechanism	Remarks
Physiologic third sound	Early diastole	Rapid filling	Good health	None	Change in tension of cusps with filling	Slow rate no gallop cadence low pitch
Protodiastolic gallop	Early diastole	Rapid filling phase	Failing heart	Failure present or imminent	Rapid equalization of pressure between auricle and ventricle	Tachycardia gallop cadence
Presystolic gallop	Presystolic	Atrial contraction	Failing heart	Failure present or imminent	Rapid equalization of pressure between auricle and ventricle	Tachycardia gallop cadence
Reduplicated first sound	Onset of systole	Preejection phase	Good health	None	Asynchronism of ventricles?	
Opening click	Early diastole	Onset of rapid filling phase	Early mitral stenosis	Indicates mitral stenosis	Rigidity of mitral cusps?	Synchronous with onset of descending limb of V wave in jugular pulse high pitch
Short early diastolic rumble	Early diastole	Rapid filling phase	Mitral stenosis auricular fibrillation	Indicates mitral stenosis	Obstruction at mitral orifice	A murmur of short duration
Audible atrial contraction	Diastole	Rapid filling phase or diastasis	Fibrosis of mitral annulus coronary sclerosis	Indicates heart block	Auricular systole	Rate usually very low
Premature beat causing single sound	Early in rapid filling				Beat very premature filling not adequate to develop enough energy to open semilunar valves hence no second sound	

In addition to the above intracardiac causes of three-sound rhythms there are several extracardiac causes including mediastinal emphysema pneumothorax air in the stomach and various unknown causes

moderate or faint pulmonary systolic murmurs as well as functional pulmonary diastolic blows (Graham Steell)

In most patients it is possible to arrive at a definitive and correct interpretation of the cause and significance of systolic murmurs However occasionally there will be doubt about a patient even after exhaustive study If there is no other evidence of cardiac disease the basal systolic murmur should be dismissed as of no significance and the patient should be emphatically reassured In the case of the apical systolic murmur it is perhaps wise to institute the proper prophylactic measures against bacterial endocarditis and against rheumatic fever and at the same time to stress the inconsequence of the murmur It is better to overlook an

Premature Beat Premature beats may arise in the atrium the junctional tissues or—much more frequently—in the ventricle (Chap 52) They are relatively more common in patients with structural cardiac disease than in healthy persons but since they are not rare in the healthy their presence has no diagnostic significance Occurring in the absence of organic heart disease premature beats may be due to emotional stress or the excessive use of tobacco coffee or tea In some instances they appear to result reflexly from distention of the stomach In many instances the cause cannot be determined The premature beat is usually recognized with ease because it consists of a contraction appearing before the next beat would ordinarily occur and is usually followed by a pause longer than the usual interval As a rule the patient is conscious of the premature beat (Chap 13) less frequently he notices the large beat after the compensatory pause

At times premature beats may occur in groups one after the other and under such circumstances the condition may be confused with auricular fibrillation an error which can be avoided by noting that the rhythm becomes regular when the heart is accelerated by exercise

One special type of premature beat merits additional comment This is *bigeminal rhythm* a state in which every alternate beat is premature This condition is usually the result of overdosage with digitalis and disappears within a few days after the drug has been withheld It should not be confused with *pulsus alternans* a disorder of rhythm in which every alternate beat is feeble but in which the rhythm remains regular In the case of both these disturbances one notes on taking the blood pressure that every alternate beat comes through at a lower level than the previous one (Chap 52) However on listening to the heart the irregularity is readily detected in the case of the bigeminal rhythm while no irregularity is noted in the case of pulsus alternans The *paradoxic pulse* which is sometimes confused with alternation or bigeminy will be discussed in the section dealing with pericarditis (p 1280)

The treatment of premature beats depends on the associated findings When they occur only occasionally and evidence of cardiac disease is lacking no treatment is needed When there exists a reasonable suspicion that tobacco or caffeine is the cause they should be withheld temporarily In excitable patients premature beats may disappear following the administration of mild sedatives The *Rauwolfia* derivatives and the other new tranquilizing drugs are often better than the barbiturates in such patients When premature beats occur in a person receiving full doses of digitalis the drug should be withdrawn for a few days if the irregularity is the result of digitalis it will then disappear In a fully digitalized patient the ingestion of a high carbohydrate meal may precipitate premature beats This is apparently related to hypopotassemia for potassium chloride (3 to 6 Gm daily in divided doses) will often abolish the arrhythmia in such persons In patients with cardiac failure digitalis in therapeutic doses may abolish premature beats Quinidine in doses of 0 1 to 0 2 Gm (1 5 to 3 gr) is a highly effective remedy for premature beats in some patients but should be given only when the extrasystoles are sufficiently frequent to cause an important mechanical inefficiency of the heart Procaine amide (Pronestyl) in doses of 250 to 500 mg orally two to four times daily is sometimes more effective than quinidine Atropine may eliminate premature beats in persons who have them only after meals

Auricular Fibrillation In the past this irregularity has been considered generally to be due to a circus movement—that is to say a wave of excitation circulating continuously in a short and irregular path about the mouths of the venae cavae (Chap 52) The irritable focus concept supported by Scherf and strongly substantiated by the thorough cinematographic studies of Prinzmetal and his colleagues is now becoming widely accepted The idea that premature beats and paroxysmal tachycardia are due to an irritable focus while auricular fibrillation and auricular flutter are dependent on a circus movement cannot be readily reconciled with the clinical facts Thus the same patient may exhibit all these different auricular arrhythmias within a few minutes Such instances support a unitary concept for the origin of all the auricular arrhythmias Some believe that auricular fibrillation may be caused either by a circus movement or by an irritable focus

Whichever may ultimately be proved to be the underlying mechanism of auricular fibrillation the effect is to obliterate the effective contraction of the atria and to bombard the atrioventricular node and the ventricles with a very rapid and irregular series of impulses Many of these impulses are blocked at the AV node but many pass through so that the ventricular contractions in the untreated patient are usually rapid and completely irregular (Chap 52)

When the rate is rapid—i e 120 or more—the diagnosis is made readily because auricular fibrillation is the only common condition in which one has the combination of a well marked tachycardia with a gross irregularity When the rate is normal or only slightly rapid as in digitalized patients the diagnosis is less readily apparent but the lack of any dominant rhythm or of any rhythmic pattern can usually be demonstrated by simultaneously listening to the heart and flexing one s finger with each beat in an attempt to determine whether there

Table 111 DIFFERENTIAL DIAGNOSIS OF THE MORE IMPORTANT APICAL DIASTOLIC MURMURS

Origin and cause of murmurs			Important points in history	Special feature of murmur	Cardiac enlargement	Important associated findings	Remarks
Murmurs arising at mitral orifice	With structural mitral disease	Mitral stenosis *	Rheumatic fever Chorea	Presystolic (regular rhythm) or early diastolic (auricular fibrillation)	Right ventricular type	Loud pulmonic second Loud first sound Systolic murmur	Very faint to moderately loud rumbling (see text) Compression of esophagus by left atrium (x ray)
		Congenital defects	Murmur since birth	Presystolic rumbling	Right ventricular type Marked enlargement of pulmonary artery (x ray)	Hilar dance (fluoroscopy)	Lutembacher's syndrome (septal defect and relative stenosis of tricuspid or mitral valve)
		Rytand's murmur	Syncopal attacks	Blowing faint often mid diastolic	Moderate to marked	Systolic murmur Heart block	Thickening or calcification of mitral annulus in elderly subjects
	Without structural mitral disease	Myxoma of left auricle	Embolism Syncope	Presystolic	Bizarre shape of auricle		Rapidly progressive heart failure
		Austin Flint murmur	Syphilis or rheumatic fever	Apical sharply localized	Left ventricular type	Outspoken signs of aortic regurgitation	Rough Presystolic no compression of esophagus by left atrium (x ray)
		Overactive heart	Palpitation	Presystolic	Slight or absent	Loud sounds systolic murmurs bounding pulse	Anemia or thyrotoxicosis (presystolic gallop resembling presystolic murmur)
Murmurs transmitted from other sites		From aortic valve	Rheumatic fever or syphilis	Loudest at base	Left ventricular type	Signs of aortic insufficiency	Blowing early diastolic
		From patent ductus arteriosus	Present since birth	Loudest at left second interspace	Enlarged pulmonary artery (x ray)	Bounding pulse High pulse pressure	Rough continuous with systolic intensification

* Mitral insufficiency with little or no stenosis may occasionally cause an apical diastolic rumble apparently due to increased flow through the mitral orifice

dence that the accompanying murmur is of the organic type It is true that thrills are simply the tactile equivalent of the auditory basis of the murmur and hence have no greater significance than the murmur itself It happens however that the kind of murmur that gives rise to vibrations that can be felt as a thrill are almost invariably of organic origin Such thrills are of especial importance in the diagnosis of aortic stenosis

DISTURBANCES OF RHYTHM AND RATE OF THE HEART

Certain disorders of the heart action are of importance because they may be responsible for serious consequences congestive failure angina pectoris or even death Others such as many of the irregularities are important because the anxiety they produce is commonly out of all proportion to their seriousness In exceptional instances the decision as to the type of irregularity has to be made by the electrocardiographic method which should be employed in all doubtful cases However the physician who has taken the time to study the arrhythmias carefully and who for a number of years has regularly correlated his clinical observations with electrocardiographic records can usually recognize the cardiac irregularities by simple auscultation

Some of the arrhythmias and especially premature beats tend to be precipitated by potassium deficiency which may be due to inadequate diet diuretic drugs or hormonal therapy

Disturbances of rhythm may be conveniently divided into two groups those which are very common and those which are less common The former group includes the sinus arrhythmia the premature beat and auricular fibrillation

Sinus Arrhythmia *Sinus arrhythmia is observed* in most healthy young persons and consists of quickening of the heart during inspiration and slowing during expiration It tends to be intensified by deep breathing and to disappear when the breath is held or when the heart rate is increased by exercise This arrhythmia has no significance

Premature Beat Premature beats may arise in the atrium the junctional tissues or—much more frequently—in the ventricle (Chap 52) They are relatively more common in patients with structural cardiac disease than in healthy persons but since they are not rare in the healthy their presence has no diagnostic significance Occurring in the absence of organic heart disease premature beats may be due to emotional stress or the excessive use of tobacco coffee or tea In some instances they appear to result reflexly from distention of the stomach In many instances the cause cannot be determined The premature beat is usually recognized with ease because it consists of a contraction appearing before the next beat would ordinarily occur and is usually followed by a pause longer than the usual interval As a rule the patient is conscious of the premature beat (Chap 13) less frequently he notices the large beat after the compensatory pause

At times premature beats may occur in groups one after the other and under such circumstances the condition may be confused with auricular fibrillation an error which can be avoided by noting that the rhythm becomes regular when the heart is accelerated by exercise

One special type of premature beat merits additional comment This is *bigeminal rhythm* a state in which every alternate beat is premature This condition is usually the result of overdosage with digitalis and disappears within a few days after the drug has been withheld It should not be confused with *pulsus alternans* a disorder of rhythm in which every alternate beat is feeble but in which the rhythm remains regular In the case of both these disturbances one notes on taking the blood pressure that every alternate beat comes through at a lower level than the previous one (Chap 52) However on listening to the heart, the irregularity is readily detected in the case of the bigeminal rhythm while no irregularity is noted in the case of pulsus alternans The *paradoxic pulse* which is sometimes confused with alternation or bigeminy will be discussed in the section dealing with pericarditis (p 1280)

The treatment of premature beats depends on the associated findings When they occur only occasionally and evidence of cardiac disease is lacking no treatment is needed When there exists a reasonable suspicion that tobacco or caffeine is the cause they should be withheld temporarily In excitable patients premature beats may disappear following the administration of mild sedatives The *Rauwolfia* derivatives and the other new tranquilizing drugs are often better than the barbiturates in such patients When premature beats occur in a person receiving full doses of digitalis the drug hould be withdrawn for a few days if the irregularity is the result of digitalis it will then disappear In a fully digitalized patient the ingestion of a high carbohydrate meal may precipitate premature beats This is apparently related to hypopotassemia for potassium chloride (3 to 6 Gm daily in divided doses) will often abolish the arrhythmia in such persons In patients with cardiac failure digitalis in therapeutic doses may abolish premature beats Quinidine in doses of 0 1 to 0 2 Gm (1.5 to 3 gr) is a highly effective remedy for premature beats in some patients but should be given only when the extrasystoles are sufficiently frequent to cause an important mechanical inefficiency of the heart Procaine amide (Pronestyl) in doses of 250 to 500 mg orally two to four times daily is sometimes more effective than quinidine Atropine may eliminate premature beats in persons who have them only after meals

Auricular Fibrillation In the past this irregularity has been considered generally to be due to a circus movement—that is to say a wave of excitation circulating continuously in a short and irregular path about the mouths of the venae cavae (Chap 52) The irritable focus concept supported by Scherf and strongly substantiated by the thorough cinematographic studies of Prinzmetal and his colleagues is now becoming widely accepted The idea that premature beats and paroxysmal tachycardia are due to an irritable focus while auricular fibrillation and auricular flutter are dependent on a circus movement cannot be readily reconciled with the clinical facts Thus the same patient may exhibit all these different auricular arrhythmias within a few minutes Such instances support a unitary concept for the origin of all the auricular arrhythmias Some believe that auricular fibrillation may be caused either by a circus movement or by an irritable focus

Whichever may ultimately be proved to be the underlying mechanism of auricular fibrillation the effect is to obliterate the effective contraction of the atria and to bombard the atrioventricular node and the ventricles with a very rapid and irregular series of impulses Many of these impulses are blocked at the AV node but many pass through so that the ventricular contractions in the untreated patient are usually rapid and completely irregular (Chap 52)

When the rate is rapid—i e 120 or more—the diagnosis is made readily because auricular fibrillation is the only common condition in which one has the combination of a well marked tachycardia with a gross irregularity When the rate is normal or only slightly rapid as in digitalized patients the diagnosis is less readily apparent but the lack of any dominant rhythm or of any rhythmic pattern can usually be demonstrated by simultaneously listening to the heart and flexing one s finger with each beat in an attempt to determine whether there

is predictability to the rhythm The distinction from numerous extrasystoles can be made by noting that while in both conditions one has beats of normal interval followed by groups of beats occurring at shorter intervals it is only in auricular fibrillation that abnormally long pauses will be noted to occur in groups of two or more More difficult and frequently impossible is the distinction of auricular fibrillation from auricular flutter with varying block and from "shifting pacemaker" in which there are auricular ectopic beats arising from multiple foci Both these conditions may produce total irregularity However since auricular fibrillation is very common while the other conditions are rare it is a safe rule to consider a person with a total irregularity in which the rhythm has no pattern and no predictability as having auricular fibrillation

Auricular fibrillation may be paroxysmal or persistent Occasionally the paroxysmal form occurs in healthy persons in whom no evidence of structural cardiac disease can be found It is also encountered in individuals who otherwise normal suffer from acute infectious diseases such as acute lobar pneumonia or in patients who are in the midst of acute illnesses primarily affecting the heart such as acute rheumatic carditis and acute myocardial infarction Rarely paroxysmal auricular fibrillation may be the consequence of anesthesia potassium deficiency digitalis intoxication or other forms of poisoning Most frequently however paroxysmal auricular fibrillation is seen in thyrotoxicosis in rheumatic heart disease with mitral stenosis or in senile heart disease In the latter two conditions the paroxysmal form not uncommonly occurs from time to time before the arrhythmia becomes permanently established The paroxysms are of variable duration lasting from a few seconds to a few days These attacks have the characteristics of all types of paroxysmal rapid heart action the onset and offset being sudden and unless the patient is observed in the midst of the attack the recognition of the nature of the episode will depend largely on the observation by the patient that the heart action is highly irregular during the attack

The permanent form of auricular fibrillation is confined almost exclusively to patients with senile heart disease mitral stenosis or thyrotoxicosis In elderly patients the usual signs of thyrotoxicosis may be absent and the presence of auricular fibrillation may be the only feature directing attention toward thyroid disease Rarely chronic auricular fibrillation may be the sole cause of congestive failure and in such instances reversion to normal rhythm is a curative procedure

The untoward effects of auricular fibrillation depend on the rapidity of the ventricular rate and the extent of the pulse deficit (i e on the proportion of ineffective and hence wasted ventricular beats) on the prior state of the affected heart on the duration of the attack and on the virtual paralysis of auricular contraction In the paroxysmal attacks the symptoms are identical with those observed in other forms of paroxysmal rapid heart action palpitation weakness dyspnea and in some cases congestive failure or prolonged anginal pain depending on the cardiac reserve or the efficiency of the coronary circulation In the chronic untreated cases the symptoms are essentially the same In cases brought under effective control by full doses of digitalis the symptoms disappear and the irregularity in itself has practically no harmful effect on the efficiency of the heart However in all cases—paroxysmal or permanent treated or untreated—the absence of atrial contractions favors the development of mural thrombi in the atria and exposes the patient to the hazards of embolism either in the lungs or in one or another of the systemic arterial branches

It is important to emphasize that when the ventricular rate fails to slow in the usual fashion in response to full therapeutic doses of digitalis the presence of thyrotoxicosis acute rheumatic carditis or pulmonary infarction should be suspected

In a patient with auricular fibrillation one faces the choice between two plans of therapy that of attempting to control the rate with digitalis the rhythm remaining irregular and that of abolishing the arrhythmia by the use of quinidine In patients with mitral stenosis quinidine is rarely effective in permanently restoring regular rhythm and appears to be especially hazardous The drug should be given with caution to patients with marked cardiac enlargement or long standing congestive failure although such patients occasionally are dramatically improved following restoration of the normal rhythm Quinidine is contraindicated when there is marked impairment of atrioventricular or intraventricular conduction because under such circumstances it may lead to fatal standstill or fibrillation of the ventricles Hence *quinidine is likely to be of greatest value in patients with recent auricular fibrillation* who are known to have had no evidences of congestive failure prior to the onset of the arrhythmia The initial dose of the drug should be small (0 1 to 0 2 Gm) and followed by a wait of several hours in order to make certain that the patient is not hypersensitive to it (as evidenced by respiratory difficulty syncope purpura) Quinidine may then be given in a dose of 0 4 Gm at 2 hr intervals for a total of five doses Conversion to normal sinus rhythm may occur while the quinidine is being administered or as is not infrequently the case may take place a number of hours after the last dose If the ectopic rhythm has not been abolished by the following morning 0 4 to 0 6 Gm (depending on the urgency of the problem) is again

given at intervals of 2 hr for five doses Only rarely will a larger dose be successful when the foregoing schedule has failed The treatment should be controlled with electrocardiograms before the third fourth and fifth doses when 0 4 Gm is administered although rarely does one encounter toxic effects for this dose If 0 6 Gm or larger amounts is given electrocardiograms should be taken just before each dose is to be given If the duration of the QRS complex or of the Q T interval has increased by 25 per cent or more or if a significant alteration in the form of the QRS has developed and *particularly if ventricular premature beats not previously present appear* quinidine should be discontinued at once It is unnecessary to control quinidine therapy by blood level estimations since so frequently conversion to normal rhythm takes place hours after maximal level has been reached and while the concentration in the blood is rapidly diminishing Quinidine should be given orally although if nausea and vomiting from one cause or another interfere with the taking of the drug preparations for intramuscular administration are available

Dangerous arrhythmias such as ventricular standstill or ventricular tachycardia may occur during quinidine therapy and manifest themselves only as brief syncopal seizures Such attacks appearing for the first time in a patient receiving quinidine make it imperative that the drug be discontinued in order to avoid a fatal termination

When the rhythm has reverted to normal maintenance doses of quinidine may be required in some patients although frequently the normal mechanism persists despite the discontinuance of quinidine

Procaine amide 0.25 to 0 5 Gm may be used in place of quinidine subject to the same precautions The two drugs may be combined but it has not been demonstrated that the combination is more effective or less toxic than either alone

The onset of auricular fibrillation in a patient who has repeatedly received mercurial diuretics or who has had prolonged anorexia may be a manifestation of potassium depletion and an indication for potassium chloride therapy

One point needs emphasis Although there are many instances of transient auricular fibrillation in which the administration of digitalis is followed shortly by the disappearance of the arrhythmia when auricular fibrillation is of long duration digitalis only rarely abolishes the arrhythmia Following the administration of this drug the atria usually continue to fibrillate However the ventricular rate diminishes strikingly and as the rate becomes slower the rhythm becomes less obviously irregular although careful observation supported by electrocardiographic tracings reveals that the ventricular irregularity does actually persist In some cases digitalis may cause a complete block at the AV node following which a regular ventricular rhythm may be seen but even here the atria continue to fibrillate

Thromboembolism is common in patients with chronic auricular fibrillation and is especially frequent in patients who also have mitral stenosis This complication is responsible for about 20 per cent of the deaths of such patients In order to prevent such episodes long term anticoagulant therapy has been advocated This is especially important in patients who have already experienced one or more thromboembolic episodes

The Less Common Arrhythmias These include the several types of heart block and the ectopic tachycardias other than auricular fibrillation

Heart Block The term *heart block* refers to a condition in which there is impairment of conduction from the atria to the ventricles through the AV node and main bundle *First degree block* is that state in which all the atrial beats are followed by ventricular beats but in which the duration of time for the passage of the impulse from the atria through the AV node and main bundle to the ventricles (P R interval) is prolonged *Second degree block* refers to a more advanced disturbance in the conduction system in which atrial impulses are from time to time incapable of penetrating the conduction system and exciting the ventricle *Third degree* or *complete heart block* describes the condition in which the conduction system is so altered that no atrial impulses reach the ventricles and the atria and ventricles beat independently at their own rhythms

FIRST DEGREE BLOCK (SIMPLE INCREASED P R INTERVAL) First degree block may be due to increased vagal tone in a perfectly normal individual or to fatigue in the conduction system as a result of prolonged tachycardia the action of digitalis or any of the inflammatory toxic degenerative or vascular processes that may affect the heart First degree block is an electrocardiographic diagnosis and produces no characteristic symptoms It may be suspected when a person suffering from rheumatic fever develops a sudden decline in the intensity of the first heart sound without any other change in the clinical picture and without evidence of fluid in the pericardium Another circumstance under which first degree heart block may be suspected clinically is when in the absence of auricular fibrillation a presystolic murmur becomes mid diastolic and ceases prior to the first heart sound First degree heart block requires no treatment the management being that of the underlying condition

It is generally considered that a P R interval greater than 0 20 to 0.21 sec represents first degree heart block and such a prolonged P R interval is held by some investigators to be evidence of myocardial disease However it is not uncommon to

and this is usually perceived by the patient The offset is likewise instantaneous but the sudden cessation of the ectopic rhythm is frequently not apparent to the patient However a story of instantaneous onset or offset if accurate allows one to know immediately that the attack represents an ectopic tachycardia of some type When the rate is less than 140 per minute the chances are *strong* that one is dealing with sinus tachycardia Rates of 170 and more per minute are almost invariably the result of ectopic rhythms and the difficulty comes chiefly in the group of patients with heart *rates between 140 and 170 When the rate is in* the general region of 150 ventricular and auricular tachycardias are unlikely and there is a distinct probability that if the rhythm is ectopic it is auricular flutter or nodal tachycardia

EXTREME SINUS TACHYCARDIA *The chief* causes of extreme sinus tachycardia are marked elevation of the body temperature severe thyrotoxicosis and any condition which produces profound circulatory collapse Occasionally acute myocardial injury due to infection infarction etc may be the cause but in most instances sinus tachycardia of severe degree is due to extracardiac causes Sinus tachycardia does not ordinarily respond significantly to carotid sinus pressure and in this respect resembles ventricular tachycardia When slowing does take place it is usually slight and neither slowing nor subsequent *acceleration* occurs with the abruptness observed in patients with auricular flutter In the absence of marked hyperthermia or severe thyrotoxicosis a patient with outspoken sinus tachycardia will usually display manifestations of forward failure (see Chap 14) *It should be emphasized* again that the differentiation between sinus and ectopic tachycardia is of the greatest practical importance because in the latter instance specific therapy aimed toward the heart may cause immediate benefit *Since sinus tachycardia requires no treatment* aside from that directed at its cause a word may be said regarding the use of digitalis in this condition Unless there are definite signs of congestive failure digitalis has no place in the treatment of sinus *tachycardia Not only is this* drug valueless under these circumstances but it may be dangerous Digitalis is not indicated merely because the heart rate is accelerated

ECTOPIC TACHYCARDIAS The most important of *these—auricular* fibrillation—has been considered already *Auricular flutter* is a much rarer but closely allied condition in which the circus movement follows a longer and more regular route or as newer observations suggest a condition fundamentally *identical* with paroxysmal auricular tachycardia differing only in that the irritable focus discharges at a much higher rate When the degree of block between atrium and *ventricle is variable* this disorder cannot be distinguished from auricular fibrillation with certainty except by the electrocardiographic method As a rule the atria beat at a rate of approximately 300 beats per minute and either 2 1 3 1 or 4 1 block exists the corresponding ventricular rates being about 150 100 or 75 When the block is constant and of high degree the condition *will usually not be suspected but if it is* suspected its presence can be confirmed by the fact that during exercise the heart rate increases suddenly rather than gradually and that in the postexercise period slowing occurs suddenly rather *than gradually In* an individual with sinus rhythm exercise causes increase in atrial rate in an individual with auricular flutter exercise has little effect on the atrial rate but the decrease in vagal tone tends to reduce the degree of block and since the *block* suddenly changes from the high degree to a lower degree the acceleration occurs in the space of a single heart beat More *commonly* with auricular flutter the ventricle responds to every alternate auricular impulse Under such circumstances the ventricular rate is usually between 140 and 160 and this fact alone should make one suspect the presence of flutter *because the other types of regular* tachycardia of ectopic origin are likely to be associated with faster rates When auricular flutter is suspected it will usually be found that carotid sinus pressure causes the ventricular rate to slow but that *the slowing is maintained only for the* brief period of the pressure and the heart then returns to the previous rate Furthermore both the deceleration and the acceleration occur instantly rather than gradually as would be the case with sinus tachycardia *if there were any response* at all to carotid sinus pressure

Occasionally the block is so variable that the high degree of ventricular irregularity is virtually identical with that observed in auricular fibrillation *The response to exercise may distinguish* the two arrhythmias in auricular flutter the irregularity may be abolished with the increased rate in auricular fibrillation the irregularity will be enhanced

Careful auscultation will frequently reveal an appreciable difference in the intensity of the first sound in auricular flutter due to slight variations in the timing of the ventricular contraction in response to the preceding atrial contraction *The principle* underlying this variability in the loudness of the first sound has been considered already This difference in the loudness of the first sound is never present in sinus tachycardia is rarely found in paroxys*mal auricular tachycardia and is frequently present* in ventricular tachycardia Hence while this sign is not specific for any one condition it can serve to limit the diagnostic possibilities when a tachycardia is first encountered

Auricular flutter is caused by essentially the same

conditions that cause auricular fibrillation has essentially the same prognostic significance and is treated in a somewhat similar manner Although the use of quinidine may occasionally cause auricular flutter to revert to normal rhythm such an effect is less likely than in the case of auricular fibrillation The usual method of treatment therefore is to administer digitalis which increases the degree of auriculoventricular block and commonly converts auricular flutter to auricular fibrillation When the drug is withdrawn such patients frequently will revert spontaneously to normal rhythm if this does not occur quinidine may be employed Occasionally it may be impossible to break up the abnormal auricular rhythm and in such an instance digitalis may be needed to maintain a degree of block sufficiently great to allow the heart rate to remain at relatively normal levels In an occasional patient digitalis will convert auricular flutter to sinus rhythm and will tend to prevent recurrences but this effect is unusual

Quinidine occasionally converts auricular fibrillation to auricular flutter Additional doses may then establish sinus rhythm or the flutter may persist The auricular rate may gradually decrease from approximately 300 to about 200 Under these circumstances the ventricular rate may suddenly increase the previous 2 1 ratio being replaced by a 1 1 ratio as the ventricle now responds to each auricular impulse When this occurs quinidine should be discontinued and digitalis administered even though this procedure may tend to cause re establishment of auricular fibrillation

When auricular flutter responds poorly to these methods of treatment and remains a serious threat because of persistent tachycardia beneficial effects may result from the administration of antithyroid drugs This procedure may also be beneficial in other types of ectopic tachycardia However the patient may have marked lassitude and other symptoms of hypothyroidism Hence antithyroid therapy should be reserved for patients who have evidence of thyrotoxicosis or if such evidence is lacking are refractory to the usual methods of treatment

Paroxysmal Auricular Tachycardia This is the most common of the ectopic tachycardias aside from auricular fibrillation (p 1241) It usually appears first in youth and attacks may continue to occur throughout life The majority of patients with this disorder display no evidence of any other cardiac abnormality *In such instances the attacks are never of serious consequence* unless they last for several days or longer However they usually produce great anxiety on the part of the patient and the family Any patient who has a history of recurrent attacks of rapid regular heart action setting in instantly and having been present since childhood or early adulthood and who displays no evidence of structural heart disease should be considered as having paroxysmal auricular tachycardia until the nature of the attacks can be established conclusively

When a patient is seen during an attack of auricular tachycardia the heart is found to be perfectly regular and the rate is usually 170 or faster Procedures which cause vagal stimulation either will have no effect or will cause the attack to cease abruptly Such procedures include pressure on the carotid sinus pressure on the eyeballs the induction of gagging or vomiting and attempted expiration with the glottis closed (the Valsalva experiment) When these several procedures attempted singly are unsuccessful they may still give a response when utilized in combination with one another

The causes of auricular tachycardia are unknown since most of the patients exhibit no signs of structural disease Prognosis as a rule is excellent even in untreated cases for the attacks tend to subside spontaneously after lasting for periods of minutes to hours Exceptionally the attacks may endure for several days and under such conditions fatigue of the heart muscle defective systolic discharge dilatation and congestive failure may supervene In the majority of the patients with this disorder the most serious aspect is the psychologic effect on the patient and on the family The attacks are alarming to them and many individuals subject to the disorder develop a secondary anxiety state which causes more suffering than the initiating disorder Hence the keystone of therapy in such a patient is proper reassurance coupled with attempts to prevent the seizures

For many patients digitalis is the most effective drug in preventing the attacks For other patients quinidine will be found to be more useful Certain patients notice that the attacks are regularly precipitated by certain trigger factors including anxiety physical fatigue abdominal distention the rapid ingestion of cold drinks and mild spontaneous hypoglycemia A careful history in regard to the exact precipitating circumstances will often enable the physician to ferret out these trigger factors and to instruct the patient how to avoid them

When a patient is seen during an attack of paroxysmal auricular tachycardia the following plan of procedure will be found effective in a considerable proportion of instances

1 Have the individual take a deep breath and attempt to expire against a closed glottis (the Valsalva maneuver)

2 Massage the carotid sinus region (first one side then the other) while listening to the heart discontinuing the massage if the rate slows abruptly

3 Carry out procedures (1) and (2) simultaneously

4 If the attack persists administer lanatoside C

(Cedilanid) 1 to 1 2 mg very slowly intravenously provided of course that the patient has not been receiving digitalis during the preceding 2 weeks

5 Repeat procedures (1) and (3) about 20 min after the injection

6 If the attack still persists neostigmine may be administered (0 5 mg) subcutaneously and the Valsalva maneuver and the carotid sinus pressure again repeated

7 Should the arrhythmia still persist the patient should be given morphine sulfate (10 to 15 mg) subcutaneously During the ensuing sleep the attack will usually cease

8 In desperate instances which are very exceptional with prolonged attacks Mecholyl may be administered in doses of 5 mg repeated every few minutes until the attack ceases or untoward symptoms develop However this drug is likely to produce alarming reactions and is rarely indicated Whenever it is employed a previously prepared solution of atropine sulfate (1 mg) should be available for use if serious toxic effects occur

The description above refers to management of attacks by the physician In addition the patient should be instructed to apply the Valsalva procedure, to utilize carotid sinus pressure to employ ocular pressure and to induce gagging and vomiting by inserting his finger into his pharynx In many instances patients learn to terminate their own attacks by these means

It should be emphasized that auricular tachycardia may produce well marked deformity of the QRS complex and this may lead to an erroneous diagnosis of ventricular tachycardia The QRS changes disappear quickly but the T wave changes may persist for several days after termination of the paroxysm and a mistaken diagnosis of myocardial infarction may be made Rarely auricular tachycardia may actually lead to myocardial infarction as the result of the diminished coronary flow resulting from the tachycardia and the increased energy expenditure of the heart

Paroxysmal Ventricular Tachycardia This is a rarer and much more serious disorder than paroxysmal auricular tachycardia The commonest cause is coronary disease and this arrhythmia frequently supervenes within a period of a few days following the development of a myocardial infarction Less commonly it is induced by the administration of digitalis in excessive amounts and very rarely the arrhythmia appears spontaneously in healthy individuals presenting no evidence of cardiac disease The diagnosis can usually be made without instrumental aid by the presence of several of the following clinical features (1) The patient commonly has evidence of coronary artery disease or has been receiving digitalis in rather large doses (2) As a rule there is no story of numerous previous attacks (3) During the attack the heart rate is usually between 160 and 210 and although it is essentially regular there may be slight variations in the regularity of the rhythm and in the intensity of the first sound from beat to beat because the relationship between atrial and ventricular contractions is somewhat variable (4) Carotid sinus stimulation has no effect on the rate

In doubtful cases electrocardiograms are necessary but even here the interpretation may be rendered difficult because auricular tachycardia which has endured for several hours often leads to conduction defects which cause the tracing to resemble that of ventricular tachycardia The electrocardiographic diagnosis cannot be made with certainty on the sole basis of the abnormal ventricular complexes In addition it is necessary that the P waves be shown to occur at a rate independent of the ventricular rate or that there be demonstrated in the intervals between attacks ventricular premature beats identical in form to the complexes seen during the paroxysm

Since it is but one step removed from the almost invariably fatal ventricular fibrillation ventricular tachycardia is the most serious of the ectopic tachycardias Fortunately quinidine is often very effective in the treatment of this condition The initial oral dose of quinidine should usually be 0 5 Gm and increasingly large doses should be given at intervals of 3 to 4 hr until the arrhythmia has broken or a dose of 1 0 Gm is given In most instances such dosage will suffice but occasionally larger doses are required

Procaine amide (Pronestyl) may also be effective in abolishing the attack and is probably safer than quinidine for intravenous use It may be administered as a slow drip in 5 per cent glucose at a rate of 500 mg per hr for 2 hr It is more effective if the patient has already received quinidine orally Either of these drugs may induce ventricular tachycardia or ventricular fibrillation They are contraindicated when these arrhythmias occur in patients with heart block (p 1243) When a patient is receiving these drugs in large dosage electrocardiograms should be made at hourly intervals Progressive widening of the QRS complex makes it likely that the drug is exerting a deleterious effect

Atropine combined with quinidine has occasionally been beneficial as have potassium chloride and magnesium sulfate

When heart failure occurs in an undigitalized patient with ventricular tachycardia digitalis should be administered The drug is not especially hazardous in such patients as was formerly believed

Nodal Tachycardia This condition is rare and is usually the result of digitalis therapy It may be suspected when an individual with a heart rate of 140 or more who has been receiving digitalis is

found to have a striking systolic pulsation in the jugular veins as the result of the simultaneous contraction of the atria and ventricles As a rule the diagnosis can be made only by electrocardiography The treatment is that of ventricular tachycardia

Clinical Picture The clinical picture presented by a patient during an attack of ectopic tachycardia varies with the age of the patient rapidity of the heart rate the duration of the attack the condition of the heart and the temperament of the patient In short attacks there may be experienced only a sense of fluttering in the chest or neck and a mild feeling of faintness the more stolid person may have no symptoms and remain unaware of the cardiac disturbance In longer attacks the characteristic features of forward failure appear more pronounced weakness and faintness the skin cool pallid and moist the systolic and the pulse pressures diminished Eventually—after days in a young normal person or after a few hours in an elderly person or in one already suffering from heart disease—congestive failure may supervene Angina may rarely appear in persons who have structurally normal hearts but it occurs more readily in those already suffering from impaired coronary circulation it is due to the increased energy expenditure of the myocardium and the reduction in coronary flow during the attack Occasionally fever may be present presumably owing in part at least to the disturbed dissipation of body heat and when this is associated with leukocytosis angina and T wave alterations of the coronary type (which may persist for some time following the cessation of the attack) confusion with myocardial infarction is possible

Some of the more important features of the ectopic tachycardias are summarized in Table 112

The value of electrocardiographic tracings in the differential diagnosis of the tachycardias is obvious Since registration of atrial activity is particularly desirable records should be obtained from the right of the sternum and in many instances while carotid sinus pressure is being applied At times the use of esophageal leads may demonstrate P waves which are not clearly seen in the conventional leads and thus clarify the nature of the arrhythmias

Harmful Effects of the Arrhythmias The physician will be much aided in management of patients presenting disturbances of the cardiac rhythm if he has a clear comprehension of the significance of such disorders When the heart rate is 28 to 30 or more the bradycardias produce certain changes in the circulation that have little or no clinical significance Owing to the large output of blood with each beat and the long diastolic pause the systolic ... ssure is elevated and the diastolic pressure is diminished The low average diastolic pressure tends to diminish coronary blood flow which occurs chiefly in diastole When the efficiency of the heart is otherwise unimpaired patients with this degree of bradycardia carry on a normal or practically normal existence When the heart rate slows to 15 or less the circulation to the brain becomes inadequate and Adams Stokes attacks occur or complete standstill or fibrillation of the ventricles leads to death

The tachycardias are important for a number of reasons Cardiac output and cerebral blood flow are diminished and although faintness is usually present actual unconsciousness rarely occurs unless the patient persists in maintaining the upright posture The tachycardias also cause marked interference with the coronary blood flow because most of the flow to the subendocardial part of the left ventricle takes place only during diastole Since the duration of systole is not much shortened with rapid heart rates the total amount of systole per minute is markedly increased and the total amount of diastole per minute is correspondingly reduced when the heart rate is excessively rapid Furthermore it should be remembered that the energy expended by the heart at each beat consists of two components of which one fraction—that used in raising the intraventricular pressure sufficiently to open the semilunar valves—is not used for the expulsion of blood At rapid heart rates the fraction of energy thereby wasted is correspondingly increased For these reasons tachycardia alone if sufficiently severe and prolonged may lead an otherwise healthy heart to fail

Aside from the deleterious effects of alterations in rate in either direction irregularity of the heart may itself be harmful This occurs when ectopic beats set in so early in diastole that the degree of ventricular filling is slight and the energy developed at the contraction is not sufficient to expel a significant amount of blood

ELECTROCARDIOGRAPHY IN RELATION TO DIAGNOSIS OF CARDIAC DISEASE

It is essential that every physician whether or not he has a primary interest in electocardiography or in diseases of the heart or even in the broader field of internal medicine have a general concept of the functions and limitations of electrocardiographic examination in the diagnosis and management of heart disease The late Frank N Wilson spoke of "the present wretched state of electrocardiographic diagnosis and the misery attributed to it In part this unfortunate situation is due to the lack of comprehension by many physicians of the kind of information electrocardiography can or cannot bring to them

In patients with arrhythmias the ECG usually

Table 112 THE MORE IMPORTANT CLINICAL FEATURES OF THE VARIOUS TYPES OF TACHYCARDIA

Condition	Common causes	Other etiologic data: Age at first attack	Other etiologic data: Heart disease	Usual heart rate	Rhythm	Effect of vagal stimulation*	Effect of digitalis	Effect of quinidine	Remarks
Sinus tachycardia	When moderate: exercise, emotion, almost any illness. When marked: hyperthermia, thyrotoxicosis, and circulatory failure	Any	Usually absent	100–160	Regular	No effect, or slight temporary slowing	None	None	Onset and end gradual (abrupt onset and end in all ectopic tachycardias)
Auricular fibrillation	Mitral stenosis, senile heart disease, thyrotoxicosis	Adults	Nearly always present	120–160 (slower when digitalized)	Totally irregular	Slight temporary slowing	Rate slowed; irregularity tends to persist †	Restores normal rhythm	The only common cause of tachycardia with gross irregularity
Auricular flutter	Mitral stenosis, senile heart disease, thyrotoxicosis	Adults	Nearly always present	About 150; 100 or 75 (with 2:1, 3:1 or 4:1 block)	Regular (rarely totally irregular)	Temporary abrupt slowing; abrupt return to rapid rate	May convert to auricular fibrillation	May restore normal rhythm	When rate is normal, exercise causes abrupt acceleration with later abrupt deceleration
Paroxysmal auricular tachycardia	Unknown	Childhood or young adulthood	Usually absent	160–220	Regular	Either no effect or abolition of attack	May relieve attack. Often prevents attacks	May relieve or prevent seizures	The only common cause of extreme tachycardia in a young adult without evidence of structural heart disease
Paroxysmal ventricular tachycardia	Coronary disease. Digitalis	Usually over 50	Nearly always present	160–220	Essentially regular with occasional slight irregularity	None	Indicated only if heart failure develops	Relieves and prevents seizures	May terminate fatally

* Including carotid sinus pressure, ocular pressure, holding breath, Valsalva experiment, induction of gagging, and induction of vomiting.
† Digitalis may abolish or prevent auricular fibrillation or flutter in some patients; this is exceptional.

yields precise information Alterations in P waves may furnish clues to the presence of mitral stenosis cor pulmonale or atrial septal defects but such clues need to be supplemented by other more decisive information

Abnormalities in the form of the ventricular complex are often erroneously evaluated There is strong evidence that the Q R S T sequence is mainly dependent on the subepicardial portions of the ventricle and that the subendocardial fibers are electrically silent Therefore subepicardial fibrosis due to such innocent causes as healed focal pericarditis or remote contusions of the heart (Fig 161) may cause impressive changes in the ECG while an extensive recent subendocardial infarction may show no significant change T waves are especially labile and may be altered by electrolyte shifts emotion tachycardia pressure on the ventricle ingestion of iced drinks or even by a carbohydrate rich meal (Fig 162) The QRS complex is less unstable and the presence of prominent Q waves in leads I or II or in the apical or left lateral precordial regions usually means focal disease of the myocardium However there is no necessary parallelism between such a change and the gravity of the clinical picture or even the nature of the underlying disease process It so happens that coronary disease is the commonest cause of focal myocardial disease but identical changes may be induced by other localized disorders such as abscess or tumor Thus except in patients with arrhythmias therapy should be based on the clinical picture Diagnosis is based on evaluation of *all* the evidence with emphasis in most instances on that derived from the clinical study

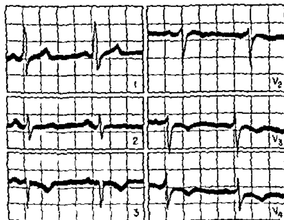

Fig 161 This 32 year-old man had been rejected for insurance because of the inverted T waves in the precordial leads These had been interpreted as evidence of coronary artery disease The history physical examination and fluoroscopic study revealed no evidence of cardiac disease The patient was able to perform vigorous and even violent exercise without any symptoms pointing toward cardiac disease

Four years previously his sternum had been fractured by impact against the steering wheel in an automobile accident The electrocardiographic changes illustrated are believed to have resulted from a contusion of the heart and are not considered to have any clinical significance The record illustrates the fallacy of placing predominant emphasis upon the electrocardiographic rather than on the clinical findings

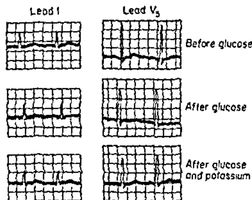

Fig 162 The patient is a healthy 44 year-old man without evidence of cardiovascular disease The T waves which were upright in the fasting state became inverted in V and isoelectric in lead I 40 min after the ingestion of 100 Gm glucose When KCl was administered with the glucose on the following day the T waves remained unchanged The record illustrates the fallacy of diagnosing coronary disease or any type of organic heart disease on the basis of T wave inversion alone

As Wilson and his coworkers stated

Electrocardiographic abnormalities are not diseases They have no important bearing upon the life expectancy of the patient or the extent to which his mode of life should be altered when there is a reasonable doubt as to the nature of the factor or factors responsible for them in that particular case

BALLISTOCARDIOGRAPHY

There is reason to believe that this method will ultimately be of great practical value because the records are related to the force of the heart beat Thus the ballistocardiogram tends to furnish an index to the quality of contraction which appears to be altered in many persons years before the quantity of contraction (output) is affected Pending further technical improvements and pending more complete knowledge of the mechanism of the various waves in normal persons the ballistocardiogram must be looked upon as a research method rather than a clinical procedure

The value of cardiac fluoroscopy has been indicated in the preceding pages

Other useful procedures in examining the heart include cardiac catheterization angiocardiography and oximetry Since these procedures are of particular value in the differential diagnosis of congenital heart disease they are discussed in Chap 225

224 ETIOLOGIC ASPECTS OF HEART DISEASE (Including Treatment of the Different Types)

William H Resnik and
T R Harrison

RHEUMATIC HEART DISEASE

Rheumatic fever was first clearly separated from gout by Sydenham (1683) More than 100 years passed before Pitcairn (1788) Edward Jenner (1789) and Wells (1810) emphasized the relationship between rheumatic fever and the subsequent development of *cardiac disease This concept* was firmly established by Bouillaud (1834) It was not until 1904 that the specific pathologic lesion characteristic of the disease was described by Aschoff

In the United States rheumatic heart disease has now assumed first rank as a cause of death among children of school age and is second only to tuberculosis as a cause of death in young adults

Acute Rheumatic Carditis

Rheumatic heart disease refers either to the active form commonly designated as acute carditis in which acute inflammatory lesions are developing or regressing or to the inactive form in which the rheumatic process has spent itself and has left behind as a residue a permanently damaged heart The two forms may occur simultaneously when an acute exacerbation of rheumatic fever takes place in an individual who already has undergone permanent structural alteration in the heart as the result of past episodes of rheumatic fever

It is now generally accepted that involvement of the heart is an almost universal phenomenon of all cases of rheumatic fever If this view is correct the concern is not whether the heart has been affected in rheumatic fever for the decision is implicit in the diagnosis The more relevant question is how seriously the heart has been affected The grades may vary from the mildest subclinical forms in which minimal lesions are present which reveal no definite clinical signs that point specifically to cardiac involvement to the types in which extensive and severe pathologic changes in the heart are unmistakably manifested by abnormal clinical signs Through common usage the term *active carditis* is generally limited to those cases in which the clinical signs of impairment of the heart are more or less definite

The combination of fever acutely inflamed joints and pericarditis raises the question of differentiation between rheumatic fever with carditis and disseminated lupus When the characteristic skin lesions of lupus erythematosus are present and L E cells are demonstrated the problem is settled in their absence it is more difficult Leukopenia red blood cells in the urine splenomegaly and lymphadenopathy are practically decisive evidence in favor of lupus Rheumatic pericarditis is invariably a manifestation of severe pancarditis and is usually associated with loud murmurs and significant prolongation of the P R interval Evidence of pericarditis without signs of valvular or myocardial injury is frequent in patients with lupus In some instances the differentiation is possible only at a later date and depends on whether the characteristic valvular lesions of chronic rheumatic heart disease have developed

Management Since treatment of acute rheumatic fever and prevention of recurrence have already been discussed (p 867) the following remarks are confined to the problems peculiar to acute rheumatic carditis Salicylates are often strikingly beneficial in controlling acute rheumatic pericarditis but are otherwise ineffective Similarly digitalis is rarely of benefit in the treatment of congestive failure or auricular fibrillation when they occur during acute rheumatic carditis

The value of adrenocortical hormones in preventing the development of permanent cardiac damage is in doubt However there appears to be sufficient evidence that the incidence of residual valvular defects can be lessened provided large enough doses of the steroids or of ACTH are administered within the first 3 weeks after the onset ACTH gel 100 to 200 mg or cortisone 300 to 500 mg or prednisone 100 to 160 mg should be given daily in divided doses at 6- to 8 hr intervals Prednisone is probably preferable since it may be given orally and since it entails a lessened risk of fluid retention The usual precautions should be observed careful observation of the blood pressure and search for evidence of excessive salt and water retention restriction of sodium intake administration of potassium chloride 1 0 Gm three times daily and of an aluminum gel to diminish the danger of peptic ulcer formation Phenoxymethyl penicillin should also be given orally 0 3 Gm (500 000 units) four times daily to destroy any residual hemolytic streptococcus organisms and to prevent so far as possible other secondary infections that might arise as a result of the hormone treatment This regime should be continued for 6 weeks and then tapered off gradually

The question of the duration and rigidity of restriction of activity in patients with acute rheumatic carditis is difficult Ideally activity should be kept at a minimum until all traces of the rheumatic process have subsided and this means bed rest with possibly a few hours in a chair and bathroom privileges when fever and tachycardia approach normality Unfortunately there is no certain test that indicates the complete cessation of rheumatic activity Persistent elevation of the sedimentation rate of the C reactive protein or of the antistreptolysin titer when not accompanied by fever tachycardia or other chemical evidence of active injury is not an indication for rigid rest

After all signs of rheumatic activity disappear physical activity may be increased gradually during a period of 2 or 3 months with frequent evaluation of the clinical state If after such time no evidence of diminished cardiac reserve or of recrudescence of rheumatic carditis appears the patient may be allowed freedom to do as he pleases provided he lives below the symptom threshold i e does not incur dyspnea or fatigue

In an individual with chronic rheumatic heart disease who is under the age of thirty five the development of *congestive failure* constitutes presumptive evidence of recurrent activity and both

conditions should be treated Even in older patients with rheumatic heart disease the presence of digitalis resistant heart failure should arouse the suspicion of active rheumatic carditis

In younger children the necessity for long continued bed rest poses a difficult problem of psychologic management Prolonged absence from school deterioration of morale and the danger of developing a lifelong anxiety state are factors that require consideration and appropriate management

Chronic Rheumatic Valvular Heart Disease

The diagnosis of chronic rheumatic heart disease rests on the recognition of the various valvular lesions that are the invariable accompaniment of this disorder

General Comments The clinical course of rheumatic heart disease varies markedly in relation to the presence or absence of repeated or persistent activity of the rheumatic process At one extreme there is the child or young adult with persistent active infection and the development within a few months of evidence of myocardial pericardial and endocardial damage In such patients it is common to witness soon thereafter the appearance of intractable and progressive congestive heart failure and death within a year or two after the onset of the initial attack At the other extreme is the middle aged person in perfect health with or without a story of fever and joint pains in youth who is discovered to have a valvular lesion (most commonly mitral regurgitation but occasionally mitral stenosis or aortic valvular disease) but without any symptoms either at rest or upon strenuous effort In such individuals the minimal valvular damage has usually resulted from a single rheumatic episode The heart has adjusted to the mechanical defect and health may remain entirely unimpaired The patient may eventually die of some unrelated process or not rarely he may develop congestive failure after the age of sixty as senile myocardial degeneration sets in Between these two extremes there is every intermediate gradation

It is of importance to note that the patients with minimal valve lesions and without symptoms of congestive failure or diminished cardiac reserve are peculiarly susceptible to the development of bacterial endocarditis a complication which rarely occurs in the presence of lesions so far advanced as to cause congestive failure

The relation of auricular fibrillation to rheumatic heart disease is of interest This complication practically never occurs in patients with involvement of the aortic valve alone It is somewhat rare when mitral regurgitation without stenosis exists However it is very common in persons with long standing mitral stenosis and in such patients the onset of auricular fibrillation frequently converts a previously asymptomatic state into congestive failure Since digitalis produces striking benefit when it slows the rate even though the total irregularity persists it is clear that the harmful effects of the arrhythmia are in part the result of the tachycardia and of the pulse deficit rather than of the irregularity Nevertheless some patients are decidedly improved by conversion to regular rhythm (p 1242) Embolic phenomena appearing in patients with rheumatic heart disease may occur as the result of infected valvular thrombi when bacterial endocarditis coexists or as the result of sterile thrombi arising in the left atrium or its appendage in patients with mitral stenosis The likelihood of the development of atrial thrombi and consequent embolism is much greater in patients with auricular fibrillation than in those with regular rhythm The seriousness of embolism depends on the size and location of the occluded artery

Prognosis Prognosis depends on a multitude of factors The first of these is the persistence or recurrence of active rheumatic carditis The second is the cardiac reserve as indicated by the exercise tolerance The duration of life tends to be shorter after onset of symptoms in patients with aortic lesions who are particularly likely to encounter angina pectoris sudden death or rapidly progressive failure Obviously the prognosis is completely uncertain in patients who have angina pectoris The prognosis of subacute bacterial endocarditis is now usually good although many patients with this condition are unfortunately left with an exaggeration of the valve lesion Previous concepts of prognosis are constantly undergoing revision as the result of the rapid advances in valvular surgery

Aortic Stenosis Aside from the rather rare instances of congenital subaortic stenosis virtually all cases of aortic stenosis up to the age of fifty are due either to congenital malformations of the valve cusps or to previous rheumatic fever Some investigators hold that all cases below the age of thirty are on a congenital basis In both instances the valves may become so distorted and sometimes so densely calcified that it may be difficult to distinguish between the two

After the age of fifty five to sixty calcific aortic stenosis is far more common in men and its etiologic basis is uncertain When mitral stenosis is also present it is logical to assume that both lesions have the same rheumatic origin When aortic valve involvement alone is concerned it is generally believed that the lesion is primarily rheumatic with secondary deposition of calcium There are some grounds for holding that the lesion may be due solely to atherosclerotic distortion of the valves In rare cases identical lesions have been found in young persons with hypercholesteremic xanthoma

tosis who lack all stigmas of previous involvement by rheumatic fever Probably the strongest evidence is that persons of fifty five or older known to have been free of any sign of valvular disease in the immediately preceding years have been observed to develop aortic stenosis almost literally under one s stethoscope

Symptoms The symptoms especially characteristic of aortic stenosis are due to the obstructive lesion that leads to an increasingly fixed cardiac output and are due also to the striking hypertrophy of the left ventricular musculature *Syncope on exertion* occurs in 10 to 20 per cent of the cases and is probably due to inability of cardiac output to increase as peripheral resistance diminishes in response to muscular exertion This leads to a sudden fall in blood pressure cerebral hypoxia and loss of consciousness This symptom has grave prognostic significance since it implies a severe obstruction death usually occurs within 3 years The hypertrophy of the left ventricle and the tremendous increase in the work of this chamber outgrow the capacity of the coronaries to supply an adequate flow of blood to the myocardium and myocardial hypoxia ensues even when the coronaries are free of significant disease *Angina pectoris* develops in about one third the patients and rarely myocardial infarction may be seen even when the coronaries are relatively normal *Sudden death* occurs in about 20 to 25 per cent

Signs The classic signs of this disorder are the loud rough systolic murmur usually heard best in the second right interspace and well transmitted into the neck the corresponding thrill the diminished or absent second aortic sound the slowly rising pulse of low volume (plateau pulse) and the presence of calcification in the region of the aortic cusps as revealed by fluoroscopy However the signs vary considerably The murmur may be loudest over the body of the heart or at the apex and it may disappear completely during congestive failure reappearing when compensation has been restored The thrill not always present is usually proportional to the loudness of the murmur but there is no necessary parallelism between the latter and the severity of the stenosis The second sound over the aortic area is well heard in about half the cases in some cases because of residual pliancy of the cusps in others because of transmission of the second pulmonic sound The character of the pulse is dependent on the degree of stenosis and is so often modified by a coexistent regurgitation that it is not of great value in diagnosis The pulse pressure is diminished in some instances but is often normal or high because of aortic insufficiency or rigidity of the aorta Calcification of the valves is absent in over half the cases and its detection is dependent on the skill and experience of the fluoroscopist The left ventricular hypertrophy is indicated by the localized thrust at the apex x ray reveals the characteristic appearance of left ventricular enlargement The electrocardiogram displays left ventricular hypertrophy unless the stenosis is slight Frequently the coved T waves of myocardial hypoxia are encountered and when the R wave is absent in the first three precordial leads differentiation from an old healed septal infarct may be difficult or impossible

When the classic textbook" findings are elicited the diagnosis is not difficult However it is important to bear in mind that the departures from this idealized picture are frequent and that aortic stenosis is still often unsuspected until revealed at the autopsy table

When congestive failure appears the outlook is usually poor death commonly resulting from increasingly refractory heart failure in 2 or 3 years However this prognosis is subject to variation depending on whether the failure is due to the severity of the stenosis or to more remediable factors such as excessive exertion or salt ingestion Occasionally one encounters a person in the seventies or eighties known to have had the characteristic signs of aortic stenosis for years and who continues to remain completely asymptomatic

Treatment Treatment consists of the usual precautionary measures against the development of subacute bacterial endocarditis and of congestive failure or angina should they occur Surgical dilatation of the valve has been successfully employed although the mortality still remains high

Aortic Insufficiency Occasionally this defect may result from a congenital bicuspid valve usually in conjunction with coarctation of the aorta In practically all other instances up to the age of thirty the lesion is due to rheumatic fever In the thirties and forties the problem is usually one of differentiation of rheumatic from syphilitic aortic regurgitation and in the late fifties and beyond from atherosclerotic disease of the aortic valves In male patients aortic insufficiency may occur as an apparent complication of rheumatoid arthritis or rheumatoid spondylitis A history of rheumatic fever and the presence of mitral stenosis and of aortic stenosis before fifty are the chief points in favor of a rheumatic origin Rarer causes of the valvular defect are bacterial endocarditis the anatomic disruption of the valve being one of the chief causes of mortality in this condition even when the infection is eradicated injury to the valve by trauma distortion of the valve by dissecting aneurysm stretching of the aortic ring in severe hypertension producing a relative aortic regurgitation fenestration of the aortic cusps and medial necrosis with widening of the root of the aorta sometimes associated with arachnodactyly (Marfan s disease)

Symptoms Pure aortic regurgitation can cause hypoxia of the myocardium and hence angina and sudden death but this occurs far less frequently than in stenosis Usually rheumatic aortic insufficiency remains asymptomatic for a long period Once dyspnea on mild effort begins seizures of paroxysmal nocturnal dyspnea are common and from this point on congestive failure tends to supervene and to progress rapidly

Signs The high pitched blowing murmur heard best at the aortic area or along the left sternal border *is the cardinal sign of this lesion Sometimes* the murmur is so faint that it can be elicited only at the end of held expiration when the patient leans forward The Austin Flint murmur mimicking mitral stenosis is frequently heard The peripheral signs are also important the wide pulse pressure the *water hammer pulse the collapsing pulse the* pistol shot sound the double Duroziez murmur and the capillary pulse—all indicative of a leak from the arterial system and of a peripheral vasodilatation Not infrequently the presence of the peripheral signs may lead to the discovery of the diastolic murmur that may have been overlooked The x ray reveals the enlargement of the left ventricle and the electrocardiogram usually is that of left ventricular hypertrophy and "strain A more reliable manifestation of left ventricular hypertrophy is the localized apical thrust

Treatment Treatment is essentially the same as that of aortic stenosis Operative reduction of the leak has been successfully accomplished by insertion of the Hufnagel plastic valve but long range evaluation of this procedure is still needed

Mitral Stenosis In mild cases dyspnea on exertion due to the obstructive effect of the mitral lesion is the outstanding symptom As the lesion becomes more advanced two types of compensatory adjustment occur the clinical picture depends in large measure upon which predominates

Rise in pressure in the left auricle and in the pulmonary veins and capillaries tends to maintain the cardiac output but at the cost of enhancing the congestion of the lungs Thus dyspnea becomes increasingly disabling and paroxysmal dyspnea sometimes culminating in fatal pulmonary edema is an ever present threat whenever cardiac flow is increased by exertion or fever or whenever a paroxysmal tachycardia propels blood through the lungs into the left atrium faster than the blood can flow from this chamber into the ventricle Recurrent hemoptyses due to the development of anastomatic channels between pulmonary veins and bronchial veins are also common Right sided failure is absent or minimal Physical examination reveals the characteristic presystolic crescendo rumble culminating in the loud sharp first sound In addition there may be an early mitral murmur which may be brief or may fill the entire diastole fusing with the presystolic murmur The opening snap is common and the second pulmonic sound is only slightly accentuated Aside from the enlarged left auricle and the small aorta the x ray is essentially negative The electrocardiogram also is negative except for the broad notched P wave

The second method of adjustment is by *increase in pulmonary arteriolar resistance* As this takes place and becomes more severe the flow through the lungs and the cardiac output diminish thus *protecting the capillaries against excessive flooding* with blood Dyspnea tends to diminish but at the price of an increasing burden on the right ventricle A clinical picture resembling cor pulmonale develops Right sided failure with venous engorgement congestion of the liver and often ascites is *prominent The chest pain resembling angina is* not uncommon If hemoptyses appear they are likely to be due to pulmonary infarcts which occur in a high percentage of patients whose emboli originate from the right auricle or leg veins Physical examination reveals the signs indicative of pulmonary hypertension the second pulmonic sound is markedly accentuated and there is a distinct systolic heave over the body of the heart Since flow through the left chambers is diminished there is a *corresponding lessening of intensity* of the presystolic and diastolic murmurs The opening snap is absent or faint X ray shows a marked enlargement of the pulmonary artery as well as of the left and right auricles and of the right ventricle Right ventricular hypertrophy is seen in the electrocardiogram

When the two effects back pressure from the stenotic valve and secondary pulmonary artery constriction are balanced the resulting clinical picture is likely to be that due to a low cardiac output with pronounced lassitude and fatigability but without pronounced pulmonary or systemic congestion The increase in pulmonary vascular resistance is due in part to organic arteriolar changes but it is mainly due to functional constriction since the increased pulmonary resistance may undergo striking improvement *following operative treatment*

A *relative mitral stenosis* with murmurs at the apex simulating mitral stenosis may be found in aortic insufficiency (Austin Flint murmur) patent ductus arteriosus and in various other disorders in which a large flow into the left side of the heart creates a disproportion between the normal mitral valve and the enlarged left ventricle Presystolic murmurs loudest in the tricuspid area may be heard in patients with atrial septal defects and appear to be due to a similar mechanism affecting the right side of the heart These several conditions may be recognized by signs of the basic disorder together with the absence of the opening snap and

the lack of prolongation of the time elapsing between the onset of excitation and the beginning of the first heart sound This Q S[1] time is usually prolonged in patients with mitral stenosis

Mitral Insufficiency Patients with slight incompetence of the mitral valve usually remain free of symptoms but are particularly susceptible to the development of bacterial endocarditis As the lesion becomes more severe dyspnea becomes increasingly pronounced and failure is apt to progress rather rapidly The first sound at the apex is soft or replaced by the loud blowing systolic murmur No opening snap can be heard The apex beat consists of the strong localized thrust indicative of left ventricular hypertrophy On x ray both the left auricle and ventricle are enlarged and systolic expansion of the left auricle may be observed A huge left auricle signifies the presence of a significant degree of mitral regurgitation The electrocardiogram reveals left ventricular hypertrophy

Combined Mitral Stenosis and Regurgitation The introduction of operative treatment for relief of mitral stenosis and the lack of benefit or even harm that occurs when a significant degree of regurgitation is present make the estimation of the relative importance of each of these functional alterations of great importance In many cases the decision can be reached only at exploration In general the more severe and significant the incompetence the louder the systolic murmur at the apex and the more pronounced are the signs of left ventricular hypertrophy by physical fluoroscopic and electrocardiographic examination In these cases the first sound at the apex lacks the characteristic sharpness and loudness of pure mitral stenosis and the opening snap is likely to be absent However one must keep in mind two important possibilities of deception While the opening snap is practically never present when serious mitral insufficiency is present a third sound—the early diastolic gallop indicative of left ventricular failure—may be heard and differentiation between the two will depend primarily on the presence of other manifestations of left ventricular enlargement on the difference in quality of the sounds and on careful timing of the sounds by phonocardiogram Another source of confusion may be the presence of a loud systolic murmur and faint or absent early diastolic or presystolic murmurs This is particularly likely to occur in the most advanced cases of mitral stenosis with severe pulmonary hypertension As already stated the diminished flow through the lungs and left heart tends to dampen the murmurs of mitral stenosis sometimes to extinction In these cases the apical thrust and other signs of left ventricular hypertrophy are absent whereas the signs of pulmonary hypertension are conspicuous [illegible] he systolic murmur tend to be loudest at the tricuspid or pulmonic area In all cases of doubt cardiac catheterization is of great importance

Tricuspid Stenosis This lesion occurs in 3 to 4 per cent of all cases of mitral stenosis The diagnosis is suspected when intractable but nonprogressive right sided heart failure is present for years with little or no dyspnea or orthopnea and when the physical signs of pulmonary hypertension (precordial systolic lift accentuated second pulmonic second sound and electrocardiographic evidence of right ventricular hypertrophy) are slight Ascites is sometimes a prominent feature as is also some degree of icterus due to persistent congestion and fibrosis of the liver A diastolic or presystolic murmur increa ed by inspiration is heard at the tricuspid area X ray reveals conspicuous dilatation of the right auricle without enlargement of the pulmonary artery and the lung fields are characteristically clear

This clinical picture is sometimes witnessed and represents the result of a malady whose preponderant effect is an obstruction at the tricuspid orifice However tricuspid stenosis occurs almost invariably in conjunction with other valvular lesions notably mitral stenosis and the clinical phenomena of "pure" tricuspid stenosis are necessarily modified by the hemodynamic consequences of these other valvular lesions Thus pulmonary congestion with dyspnea on exertion may be a prominent feature even though tricuspid stenosis is present In practice diagnosis of the latter lesion is difficult and frequently missed The only certain method of establishing the diagnosis is by cardiac catheterization and demonstrating a distinct diastolic pressure gradient between right atrium and ventricle

The clinical picture of tricuspid stenosis may be mimicked by more common disorders Thus the Bernheim syndrome is said to occur when a person with a left sided lesion such as aortic stenosis displays the picture of right sided failure and minimal or no evidence of pulmonary congestion This condition has been ascribed to encroachment of a displaced interventricular septum on the right ventricular cavity with impairment of right ventricular filling and flow to the lungs Catheter studies have demonstrated however that pulmonary vascular resistance in such a case is increased indicating the presence of left as well as right ventricular failure Absence of dyspnea is due not only to the impaired blood flow to and from the right ventricle but also to the increased pulmonary arteriolar resistance protecting the capillaries from engorgement

Tricuspid Insufficiency This lesion may be due to congenital displacement of the tricuspid valve (Ebstein's disease) Organic tricuspid insufficiency may also be present when associated with a tri

cuspid stenosis of rheumatic origin The usual cause for this valvular defect is functional stretching of the tricuspid ring and imperfect closure of the leaflets due to right ventricular failure commonly secondary to left sided failure When tricuspid stenosis can be diagnosed with assurance a coexistent organic insufficiency of the valve may be suspected when there is pronounced systolic pulsation of the neck veins and an expansile systolic pulsation of the liver determined by bimanual palpation

Pulmonic Insufficiency Organic disease of the pulmonary valve is practically never of rheumatic origin However functional pulmonary insufficiency with a Graham Steell murmur is common in patients with mitral stenosis and congenital heart disease that is in any condition characterized by a *marked elevation of pressure in the pulmonary artery* The Graham Steell murmur is nearly always faint (grade 1 to 2) and is usually heard best in the left second and third interspaces Differentiation of this murmur from the faint murmur of aortic insufficiency is difficult or impossible unless the peripheral signs of aortic insufficiency are so pronounced as to make the existence of the latter lesion certain In the presence of aortic incompetence and a condition causing pulmonary hypertension the coexistence of a Graham Steell murmur is impossible to ascertain and is not of much importance

Pulmonic Stenosis Pulmonic stenosis due to rheumatic fever is also a rarity Almost invariably this lesion is of congenital origin except for the unusual instances in which it occurs with malignant carcinoid practically always with liver metastases

Surgical Treatment of Rheumatic Valvular Disease

Mitral Stenosis The ideal patient for operation is aged thirty to forty five with progressive exertional dyspnea *which is beginning to interfere seriously* with normal activity with a well marked diastolic rumble and no other murmurs and with clinical electrocardiographic or radiologic evidence of right ventricular hypertrophy but little or no increase in the transverse diameter of the heart If in addition there is a history of hemoptysis of attacks of pulmonary edema or of systemic embolism in such an individual operation is almost imperative *The presence of right sided heart failure* likewise should be considered a reason for carrying out the procedure rather than for postponing it

The absolute contraindications are (1) bacterial endocarditis (2) obvious and outspoken rheumatic activity (3) pronounced mitral insufficiency and (4) clear evidence of mechanically important aortic insufficiency or aortic stenosis unless the aortic valve is to be attacked also

A large percentage of the patients will neither fall into the ideal group nor present the absolute contraindications and then sound clinical judgment comes into play This must be based not only on the clinical evaluation and at times on catheterization data but also on a consideration of the patient s disabilities in relation to his age occupation economic circumstances family responsibility and emotional reactions

It is first necessary to be certain that the patient has mitral stenosis and that the symptoms are due to this lesion and not to some coexistent disorder such as an anxiety state Definitive evidence—clinical radiologic or electrocardiographic—of right ventricular hypertrophy should be present Occasionally it will be doubtful as to whether an apparent presystolic rumble is truly a rumble or a presystolic gallop with a split first heart sound and whether the obvious right ventricular hypertrophy is the result of cor pulmonale or of mitral stenosis In such a case left heart catheterization or the measurement of the *pulmonary capillary* pressure (PC) by cardiac catheterization may furnish decisive evidence The left atrial and pulmonary capillary pressures are not elevated in patients with cor pulmonale but are elevated in individuals with symptomatic mitral stenosis Both conditions of course cause elevation of pressures in the pulmonary artery right ventricle and right auricle

Patients with auricular septal defects and other disorders which increase markedly the blood flow through the tricuspid or mitral orifice may have diastolic rumbles without mitral stenosis In such patients the evaluation of the hemodynamic state may require catheterization of both sides of the heart The presence of a marked conduction defect in the electrocardiogram of a patient with a diastolic rumble should raise the question of an auricular septal defect

A faint apical systolic murmur is not necessarily a contraindication nor is a grade I to III systolic murmur heard loudest in the pulmonic area and unassociated with evidence of aortic stenosis A loud apical systolic murmur (grade III or more) makes it probable that there is a well marked mitral insufficiency even though there is no absolute agreement between the loudness of the murmur and the size of the jet as determined at operation *In a few patients* excellent results have been obtained despite the preoperative presence of signs of outspoken insufficiency as well as stenosis However they are exceptional and in most patients with such findings the postoperative improvement has been slight It is possible that improved operative techniques for reducing the degree of regurgitation will lead to better future results in patients with mitral insufficiency In the meantime catheteri

zation of the left atrium and ventricle with the demonstration of a pronounced diastolic pressure gradient between the two chambers should be a preliminary to operation in a patient of this type The contours of the left atrial pressure curve may yield significant information concerning the relative degrees of stenosis and insufficiency One should be cautious about operation upon a patient with a grade III apical systolic murmur and a short diastolic rumble particularly when there is evidence of left ventricular hypertrophy and an undoubted opening snap is absent In such a patient the rumble may be due to rapid diastolic flow through the mitral orifice with little or no stenosis

Functional pulmonary insufficiency with a Graham Steell murmur is common in patients with mitral stenosis and must be differentiated from aortic insufficiency (Table 110 p 1239) The operation should not be done in a patient who has a basal diastolic blow and who also presents the peripheral signs of aortic insufficiency However when the pulse pressure is less than 40 ml Hg and evidence of left ventricular hypertrophy is absent the presence of a faint diastolic blow is not a contraindication to mitral valvulotomy

When there is unmistakable evidence of well marked left ventricular hypertrophy the likelihood of a good result from the operative procedure is sharply reduced because the chances are strong that the patient has an aortic lesion severe rheumatic myocarditis or outspoken mitral insufficiency

Slight to moderate enlargement of the left atrium speaks for mitral stenosis but a giant left atrium is evidence for pronounced mitral insufficiency and makes it unlikely that a strikingly beneficial effect will be achieved unless the regurgitation can be repaired also

Auricular fibrillation is not a contraindication but if other things are equal the results are likely to be better in patients with regular rhythm

Minimal clinical evidence of smoldering rheumatic activity as indicated by a rapid sedimentation rate or very slight fever is not a contraindication provided one is certain that the mitral stenosis is of long standing and is not the result of edema of the valves Catheterization of the right side of the heart with measurements of the effects of exercise and of digitalis on the pulmonary artery pressure may yield important information as to whether the heart failure is the result of a mechanical valvular lesion or of the myocardial disease

Whether or not auricular fibrillation is present a history of embolism is an indication for operation if preceded by several weeks of anticoagulant therapy

Advanced heart failure is not a contraindication provided one is satisfied that mitral stenosis is the sole cause or even the chief cause of heart failure

A history of acute pericarditis in the past is not a contraindication but adhesions may add to the operative difficulty

Knowledge from long term observation that the signs of mitral stenosis are of recent origin is a contraindication because there is the possibility that the rumble is the result of edema of the valves and that the apparent lesion may disappear with time and with treatment of the rheumatic process

The operation may be done at any age but probably the most desirable range is thirty to forty five years i e after the age of the greatest likelihood of acute flares of rheumatic activity has passed and before senescence of the myocardium has begun

Pregnancy is not an absolute contraindication to the operation but in general the procedure should be postponed until after delivery

Opinions differ as to the long range results Although the operative treatment has now been applied to thousands of patients with mitral stenosis there is still no general agreement concerning the value of the procedure or the criteria for selection of patients Some excellent and critical observers still report a high mortality believe that significant improvement occurs in only a minority of the patients and deem cardiac catheterization essential for proper selection However others report a relatively low mortality (less than 3 per cent) find that the results are good to excellent in the majority of patients submitted to the procedure and consider catheterization necessary in only an occasional instance It is the opinion of the writers that right heart catheterization is indicated when there is doubt concerning the relative importance of myocardial and mechanical factors as well as when the clinical findings suggest tricuspid stenosis Left heart catheterization may help in determining the relative degrees of stenosis and insufficiency of the mitral valve

In the experience of the writers the operative mortality should not be more than 2 per cent if the patients are selected and managed properly Clinical improvement has been striking in many of the patients and sufficient to justify the procedure in most of the others Failure to improve has usually occurred only in individuals who have presented one or more of the contraindications already discussed

The Postcommissurotomy Syndrome This syndrome consisting of pain in the precordium or in the neck is common It may develop a few days or several weeks after the operation and may last for several days only or for a number of months Some investigators have attributed this to reactivation of the rheumatic process others to irritation

cuspid stenosis of rheumatic origin The usual cause for this valvular defect is functional stretching of the tricuspid ring and imperfect closure of the leaflets due to right ventricular failure commonly secondary to left sided failure When tricuspid stenosis can be diagnosed with assurance a coexistent organic insufficiency of the valve may be suspected when there is pronounced systolic pulsation of the neck veins and an expansile systolic pulsation of the liver determined by bimanual palpation

of the pericardium resulting from seepage of blood Cortisone and allied drugs are usually of benefit

Other Valvular Deformities *Tricuspid lesions* constitute an especial problem They are nearly always associated with mitral lesions and the co existent tricuspid disease is not a contraindication to the operation for mitral stenosis The problem is to decide whether to operate on both valves or on the mitral valve alone In most cases this can be decided preoperatively

When a patient who presents clear evidence of mitral stenosis and who is a candidate for opera tive management exhibits signs suggesting tricus pid disease cardiac catheterization should be done in order to measure the diastolic pressure gradient between the right atrium and the right ventricle A gradient of 5 mm Hg or more at the end of diastole is strong evidence for tricuspid stenosis *and makes it desirable that this valve as well as the* mitral valve be dilated at the forthcoming opera tion Tricuspid insufficiency whether organic" or relative is not a contraindication to mitral valvu lotomy

The operative treatment of *aortic insufficiency* and *mitral insufficiency* is still in the experimental stage *Aortic stenosis* is being operated upon suc cessfully by a few surgeons but the technical prob *lems are not yet solved and the mortality remains* high The procedure may result in the production or aggravation of aortic insufficiency even though the stenosis may be improved Once heart failure begins in a patient with aortic stenosis the outlook is extremely poor with conservative management Therefore the attempt at operative correction is justifiable despite the hazard

CORONARY DISEASE

A sharp distinction must be drawn between anatomic and functional disorders of the coronary arteries Seventy per cent of persons beyond the age of fifty have advanced changes in one or more of the larger coronary arteries Atheroma with out significant narrowing probably predisposes to thrombosis and infarction but cannot be diagnosed clinically Marked narrowing even to the point of complete occlusion may exist and cause no clinical manifestations whatever if the collateral circulation is completely adequate There are other instances in which outspoken coronary narrowing without sig nificant myocardial scarring is found at autopsy in elderly patients who during life had congestive fail ure but never presented evidence of angina or of infarction The relative significance of the coronary disease and of the more subtle functional changes due to aging in the production of the congestive failure is uncertain at present Similarly there is uncertainty as to which of the factors is responsible for the outspoken ballistocardiographic abnormali ties so frequently found in such patients The fol lowing discussion is not concerned with asympto matic and clinically unimportant coronary disease nor with those instances of congestive failure in which coronary disease is present but of uncertain clinical significance The concern is rather with those clinical patterns which are specifically and characteristically related to coronary disease

The distinguishing clinical features of sclerosis of the coronary arteries are evidence of past or present myocardial infarction or a history of pain of the anginal type Occasionally a patient may suffer a painless infarction of the myocardium initi ating cardiac symptoms whose origin is clarified by serial electrocardiograms that leave little doubt that coronary disease is present or an electrocardiogram may reveal such characteristic changes in the QRS *complexes as could have resulted from an infarc* tion for which the patient can give no equivalent history Barring these exceptions the diagnosis of coronary sclerosis cannot be made with confidence in the absence of a history of anginal pain or of myocardial infarction and it is only when the manifestations just described are present that the term *arteriosclerotic heart disease* can properly be applied The common use of this diagnosis in elderly *persons with* cardiac *enlargement and congestive* failure in the absence of hypertensive or valvular disease or anginal pain does not at present rest on convincing evidence *The finding of thickening of the radial and brachial arteries does not justify the conclusion that sclerosis of the coronary arteries is present* Actually there is no parallelism between the two processes

Etiology Coronary arteriosclerosis is far more *common in men than in women* The cause of this sex discrepancy has been obscure although there is now evidence that hormonal influences as well as a usually greater internal thickness of the coronary arteries in males may account at least in part for the difference in susceptibility

Aside from the experimental observations that suggest the concept that atherosclerosis represents a disorder of cholesterol metabolism an impressive body of clinical evidence points in the same direc tion This evidence is considered in Chap 228

Clinical Picture The clinical pictures induced by coronary arteriosclerosis are variable In a large percentage of instances no manifestations of illness occur despite extensive disease of these vessels In other individuals relatively slight disease may be associated with severe anginal attacks and sudden death It is apparent that the degree of arterio sclerosis is less important than its rate of develop ment *especially in relation to* the rate of develop ment of collateral circulation through other chan nels When coronary sclerosis does induce clinical

more commonly men past their fiftieth year that they are seized while walking especially if uphill and soon after eating with a painful strangling sensation behind the breastbone that the moment they stand still the pain begins to subside He also pointed out that the pain often extends into the left arm and may appear only here less commonly it appears in the right arm Finally he was familiar with the remarkable termination of the disorder For if no accident intervenes but the disease go on to its height the patients all suddenly fall down and perish immediately

The deviations from this pattern are rather infrequent but they are frequent enough so that some of the more important ones deserve mention Rarely the patient will insist that the pain is burning not constrictive It is not uncommon for the anginal pain to be attributed to indigestion because it occurs after eating but in the majority of such cases the pain is actually precipitated by exercise which happens to be taken immediately after a meal In a small group of patients the pain occurs after a meal even though the patient remains completely at rest Indeed in some of these individuals angina of effort may be absent This unusual behavior is open to two interpretations It may be that some persons are particularly susceptible to the reflex coronary constriction known to occur with distention of abdominal viscera On the other hand it is possible that in such patients increased cardiac output during digestion is not attended by a decline in peripheral resistance such as occurs during exercise Thus the load on the heart after eating may be greater than during walking

Some patients experience their initial attacks only on assuming the recumbent position especially on retiring only later does the angina of effort appear In other patients typical angina appears *not during* the exertion but *immediately after* if they happen to remain quiet in the upright position In these individuals postural hypotension is present and the fall in mean aortic pressure may be sufficient to reduce coronary flow to the point where myocardial hypoxia and anginal pain at rest appear This is particularly likely to happen in persons receiving ganglionic blocking drugs for the treatment of hypertension

Finally the location of the anginal pain may differ from the usual site and offer some difficulty of interpretation Radiation int[illegible] and to the angles of the lower jaw is n[illegible] and the pain may be felt only h[illegible] the pain may be experienced only [illegible] neck at about the level of the l[illegible] or in the left supras[illegible] he left shoulder

The differential [illegible] well as the [illegible]

cussed in a preceding chapter (Chap 4 pp 28 to 33) and need not be discussed here However it should be emphasized again that the response of the pain to exercise and to nitroglycerin as determined by the history and especially by direct observation is usually of much more value than the widely used rule of thumb electrocardiographic studies during hypoxia or exercise Indeed the latter may be misleading

Prognosis Prognosis is more uncertain in this disorder than in any other chronic disease Attacks may cease either following myocardial infarction with destruction of the area responsible for the pain or spontaneously as the result of the development of collateral circulation Apparent recovery may also occur when the individual learns to avoid the precipitating factors In some patients the disorder persists in an essentially static stage for many years the exercise tolerance remaining almost unchanged Increase in severity and frequency of the attacks may follow myocardial infarction and in such individuals it is presumed that the coronary branches are diffusely affected and that the increase in work of the remaining myocardium following destruction of one portion by disease causes the aggravation The important point is that even in patients with an apparently mild form of the disease i e mild in the sense that the pain is minimal and the attacks infrequent sudden death may occur at any time In general however the prognosis is worse when the pain sets in frequently or is of great severity and long duration and is particularly bad when the attacks occur at rest independently of any known precipitating factor

Treatment The management of angina pectoris is frequently effective in ameliorating *symptoms* but rarely completely successful since extensive and irreversible changes are already present throughout the entire coronary tree by the time angina is first manifested The aim is to prevent or halt the progression of further coronary obstruction and to permit the growth of adequate collaterals to the involved areas of myocardial hypoxia Occasionally one does encounter a patient whose angina disappears completely and who lives out a normal life span dying of some unrelated disorder

The tolerance of effort varies so widely that precise directions regarding the amount of permissible exercise cannot be given However the physician can perform a useful service if he emphasizes the principle that any exercise or activity causing pain should be avoided while those not causing pain may be undertaken Exercise below the threshold of pain has never been shown to be harmful and it is possible or even probable that exercise in moderation and always kept below the degree of effort *which induces attacks may have a beneficial effect* Many patients seem to improve when they begin

manifestations either angina pectoris or myocardial infarction may occur As the result of repeated infarction with loss of functioning heart muscle dilatation and congestive failure may supervene However the cardinal clinical pictures associated with coronary arteriosclerosis are those of angina pectoris and of myocardial infarction and these conditions will therefore be discussed in some detail

Angina Pectoris

This disorder may be defined as a clinical syndrome brought about by a temporary discrepancy between oxygen supply and oxygen need in the heart and characterized by a particular type of pain as well as by the likelihood of sudden death Angina pectoris is not a disease in the sense of an etiologic or morphologic entity but like diabetes represents a clinical and physiologic entity The disorder was first clearly delineated by William Heberden whose classic description is a model of astute observation and clear expression

The restriction of the term *angina pectoris* to indicate the pain alone rather than the total syndrome of which the pain is one important feature is justified on neither historical nor clinical grounds

Etiologic Factors Age and sex are important the disease is most common in males beyond the fiftieth year but is observed sometimes as early as the second or third decade In the absence of hypertension or diabetes angina pectoris is rare in women below the age of sixty The other predisposing factors are those which have been mentioned as tending to produce coronary arteriosclerosis—viz obesity diabetes myxedema xanthomatosis and other hypercholesteremic states and the disorders which tend to affect the aortic valve including rheumatic fever and syphilis

The question of the relation of hypertension to angina pectoris is of some importance There is ample evidence that hypertension favors the development of coronary arteriosclerosis The increased work of the heart tends to increase the oxygen needs of the myocardium The increased intramural pressure during systole tends to diminish the systolic coronary flow to the subendocardial portions of the left ventricle On the other hand the higher head of pressure in the aorta tends to increase the systolic flow to the outer portions of the left ventricle and the flow during diastole to the whole heart tends to be elevated as the result of the rise in diastolic blood pressure The over all results of these opposing factors is that angina pectoris is considerably more likely to occur in hypertensive persons than in individuals with normal blood pressure

Aside from the uncommon instances of periarteritis in which coronary involvement causes angina there are scattered reports in the literature of typical cases of angina pectoris occurring in individuals who at autopsy have revealed no gross obstruction of the coronaries and only myocardial involvement by sarcoid scleroderma hemosiderosis amyloid fatty infiltration and endocardial fibroelastosis Presumably in each instance a tiny coronary branch has been narrowed These cases are of interest only as medical curiosities and of importance only at a clinical pathologic conference

The *precipitating causes* (i e the conditions which tend to induce an attack in persons with one of the underlying disorders mentioned) include exercise emotion eating and cold as the most common agents When attacks occur at rest in the absence of these factors they are much more likely to appear in the recumbent than in the sitting or standing postures Such attacks during recumbency are especially likely to occur during sleep Hypoglycemia either induced by insulin or of the spontaneous type is a less frequent precipitating factor but is of considerable practical importance The various types of ectopic tachycardia may induce attacks in predisposed patients and rarely may cause anginal seizures in individuals without disease of the coronary arteries and with structurally normal hearts Since the duration of systole is relatively constant and varies only slightly with variations in heart rate the total amount of systole per minute is increased and the total duration of diastole per minute correspondingly decreased during tachycardia The coronary flow to the fibers of the inner part of the left ventricle tends to be shut off during systole This factor when added to the factor of increased energy expenditure by the heart probably accounts for the occasional occurrence of anginal attacks during seizures of paroxysmal tachycardia in individuals with structurally normal hearts

Of especial importance because of their frequency are attacks of angina occurring during sleep In a few such instances a history indicating nightmares ectopic rhythms or hypoglycemia as the precipitating cause of such attacks can be obtained More common are those patients in which nocturnal reabsorption of fluid from the legs is responsible In such patients the attacks of pain are often associated with dyspnea and both symptoms may be prevented or diminished by restriction of sodium intake and the use of mercurial diuretics However there are other patients in whom no precipitating factor can be found for repeated attacks which awaken the patient from sleep The cause of such anginal attacks is obscure The work of the heart in many elderly persons is greater when the patient is recumbent than when he is sitting

Clinical Picture The majority of patients with angina pectoris give histories that conform closely to the classic pattern originally described so vividly and precisely by William Heberden in 1768 He pointed out that the subjects of the malady are

to take a short walk at a slow pace twice daily after taking a nitroglycerin tablet The distance of the walk should be increased gradually as the exercise tolerance rises Whether the benefits sometimes observed from such a regime are to be attributed to the development of increased collateral circulation in the coronary system or are of psychic origin i e restoration of confidence in a previously frightened patient remains uncertain The patient should be warned that attacks are more easily precipitated if he exerts himself shortly after eating or on a cold windy day and that appropriate reduction in his activity under these circumstances should be made The harmful effects of emotional strain should be particularly emphasized and when necessary a mild sedative or tranquilizer administered

The role of anemia thyrotoxicosis hypoglycemia obesity and paroxysmal tachycardia as possible contributing factors should be kept in mind for these conditions though rather uncommon in patients with angina pectoris are usually readily amenable to treatment

The problem of diet remains highly controversial The importance of cholesterol intake of the amount and kind of fat consumed and of other factors is not yet established For the present the authors believe that the preponderance of evidence suggests the advisability of restricting all fats although recent work indicating the beneficial effect of unsaturated fatty acids (natural vegetable and marine oils) may necessitate a revision of the low fat concept at least for some individuals

The value of beta sitosterol (Cytellin) is sufficiently suggestive to warrant its trial for those who can afford it One to four tablespoonfuls taken with each meal may be required It is probable that beta sitosterol acts by blocking the absorption of cholesterol from the intestinal tract There is no valid evidence for believing that the administration of choline and methionine is of benefit

Large doses of nicotinic acid (1 500 mg after each meal) have been reported to have a favorable effect in lowering the blood cholesterol in patients who can tolerate the flushing and headache which this treatment may produce These untoward effects may be minimized by starting with much smaller doses and gradually increasing them

There is increasing evidence both statistical and experimental that administration of heparin may have a beneficial effect in retarding the development of atherosclerosis and on the clinical course of coronary disease Heparin exerts a complex effect and the factors responsible for the favorable effect on atherogenesis are not known It is believed that the chief factors are the reduction of beta lipoproteins and the removal of fatty coatings from the wall of the intima The anticoagulant effect of heparin in the doses employed is considered to play no role Aqueous heparin is given subcutaneously in doses of 200 mg twice weekly or 150 mg three times weekly Optimal dosage schedules remain to be established

The reversal of the abnormal blood lipoprotein pattern to a more normal one under the influence of estrogens constitutes the basis for the employment of the latter hormones in patients with coronary disease However the feminizing effects with the necessary amounts of estrogens make this method of treatment impracticable for most men Thyroid extract should be administered only with great caution to persons who reveal by accurate tests such as the protein bound iodine an unquestionable hypothyroidism

The treatment of the attack is accomplished most surely by the sublingual administration of nitroglycerin The dose should be sufficient to relieve the attack and slightly less than that which induces flushing of the face and headache 0 15 mg (gr 1/400) to 0 6 mg (gr 1/100) Compared to nitroglycerin other drugs are of relatively little value although occasionally one of the longer acting coronary dilators such as pentaerythrol tetranitrate (Peritrate) 10 to 20 mg t i d may be employed with benefit Rarely a patient with angina and mild postural hypotension may develop syncopal attacks on taking nitroglycerin and such persons should be instructed to lie down immediately after taking the tablet Many patients are reluctant to take nitroglycerin because of the name of the drug or because they will get used to it" so that it may no longer be effective "when they really need it These persons should be assured that it may be safely employed if properly taken not more than 1 tablet every 15 min and that habituation rarely occurs and that the effect is not lost with time although tolerance may be somewhat increased In fact patients should be encouraged to use the drug prophylactically in an attempt to prevent attacks when conditions arise that are likely to lead to seizures

Patients with frequent anginal attacks and especially those with attacks during sleep may be strikingly benefited by the use of nitroglycerin ointment (Nitrol) which the authors have found to be the most effective of the long acting coronary dilators The ointment is spread as thinly as possible (but not rubbed) over the chest abdomen or thighs It is applied every 2 to 4 hr the maximal amount being that which is just short of producing headache —in most patients ½ to 2½ in ointment per dose The beneficial effect lasts 2 to 4 hr The exact dosage and frequency of application of the ointment varies from patient to patient In properly selected cases the improvement resulting from its use may be so striking as to outweigh the dis

The treatment of the attack is accomplished most surely by the sublingual administration of nitroglycerin The dose should be sufficient to relieve the attack and slightly less than that which induces flushing of the face and headache 0 15 mg (gr 1/400) to 0 6 mg (gr 1/100) Compared to nitroglycerin other drugs are of relatively little value although occasionally one of the longer acting coronary dilators such as pentaerythrol tetranitrate (Peritrate) 10 to 20 mg t.i.d may be employed with benefit Rarely a patient with angina and mild postural hypotension may develop syncopal attacks on taking nitroglycerin and such persons should be instructed to lie down immediately after taking the tablet. Many patients are reluctant to take nitroglycerin because of the name of the drug or because they will "get used to it," so that it may no longer be effective "when they really need it." These persons should be assured that it may be safely employed if properly taken, not more than 1 tablet every 15 min and that habituation rarely occurs and that the effect is not lost with time although tolerance may be somewhat increased In fact patients should be encouraged to use the drug prophylactically in an attempt to prevent attacks when conditions arise that are likely to lead to seizures

Patients with frequent anginal attacks and especially those with attacks during sleep may be strikingly benefited by the use of nitroglycerin ointment (Nitrol) which the authors have found to be the most effective of the long acting coronary dilators The ointment is spread as thinly as possible (but not rubbed) over the chest abdomen or thighs It is applied every 2 to 4 hr the maximal amount being that which is just short of producing headache —in most patients ½ to 2½ in. ointment per dose The beneficial effect lasts 2 to 4 hr The exact dosage and frequency of application of the ointment varies from patient to patient In properly selected cases the improvement resulting from its use may be so striking as to outweigh the dis

advantages of the cost and its rather unpleasant mode of administration There are certain precau *tions to be observed in its use Postural* hypotension may be induced in elderly patients and tolerance to nitroglycerin may become so increased as to ne cessitate very large doses when sublingual tablets are employed for relief of individual attacks An ginal attacks considerably enhanced in frequency and severity may return if the ointment is suddenly withdrawn Reduction of the dose should be ef fected gradually and over a period of weeks To repeat *the ointment is recommended primarily for the prevention of attacks occurring frequently and particularly when unrelated to exertion*

Patients whose angina is due to aortic stenosis and who do not suffer from myocardial failure have *been relieved of the angina by aortic valve com* missurotomy although the risk of the operation is still considerable

In patients with nocturnal angina sodium re striction and mercurial diuretics are often valuable especially when there is dyspnea associated with the pain

Anginal pain may be relieved by interruption of appropriate nerve pathways but this type of pro cedure is practically never required The various surgical operations aimed at increasing coronary flow are still in the experimental stage

Tobacco should be restricted to a few cigarettes a day or given up completely This advice is espe cially important if smoking can be demonstrated to cause anginal pain premature beats or pro nounced increase in heart rate or blood pressure Alcohol in moderation is permissible and indeed desirable if experience indicates that for the par *ticular individual it exerts a relaxing influence* Cof fee is allowed provided it does not cause palpitation and sleeplessness

Preinfarctional Angina

The choice of a suitable designation for the inter mediate form of coronary pain one that does not fall into the category of effort angina of brief dura tion or the prolonged pain with unquestionable manifestations of myocardial necrosis is difficult Coronary insufficiency and coronary failure are not accurate *since any pain due to hypoxia of the* myocardium whether brief or prolonged is due to insufficiency or failure of the coronary circulation Status anginosus simply implies a prolonged pain but does not indicate whether or not infarction is present Prolonged angina without evidence of myocardial necrosis" appears to be the most ac curate designation but is clumsy The authors sug gest *preinfarctional angina* not because it is free of objections but since prolonged angina is actually a forerunner of infarction in many instances and since from a physiologic standpoint it is but one step away from the stage of myocardial necrosis it appears to them to be the most descriptive of the condition under consideration

Prolonged and usually severe anginal attacks appearing at rest or with minimal exertion are likely to be observed under any of three condi tions In a few patients they may be induced by an *increased load on the heart* such as severe emo tional stress an unusually large meal an episode of hypoglycemia or the excessive ingestion of salt When the cause is removed the patient will usually return to the previous state *having only brief and* milder pain with exertion

Less frequently severe and prolonged angina is initiated by some condition such as dehydration hemorrhage shock ectopic tachycardia or pulmon ary embolism which *reduces cardiac output* and thus causes further decline in blood flow through a coronary system already compromised by atherom atous disease Of particular importance are those instances in which the circulatory failure induced by an initial myocardial infarction leads to ischemic pain in other myocardial regions and thus to the threat of a second and more serious infarction within a few days after the first

More commonly however these prolonged and severe anginal attacks are not associated with demonstrable increase in load or decline in output but apparently with a slow progression of coronary atheroma and an *increasingly unfavorable balance between narrowing of main branches and widening of collateral channels* The patient now begins to have attacks of increasing severity and duration on less and less exertion and to be awakened fre quently by the seizures This is the usual type *of preinfarctional angina Electrocardiographic* changes may be absent or minimal but records obtained during an attack of pain will usually ex hibit depression of S T segments

The distinction between preinfarctional angina and myocardial infarction *depends largely upon* the absence or presence of the signs of tissue necrosis (leukocytosis elevation of serum transami nase fever and an abnormally rapid sedimentation rate) Other features pointing toward infarction include even longer duration of pain *failure of benefit from glyceryl trinitrite the appearance of* a pericardial friction rub development of pulmonary edema and circulatory collapse presence of Q waves and elevation of the S T segment in appropriate electrocardiographic leads The distinction between the two conditions is somewhat artificial because careful study indicates that many of the patients with typical preinfarctional angina display clear evidence of necrosis (transient leukocytosis mini *mal fever elevation of the sedimentation rate) even* though the other manifestations of infarction are absent In such instances one is presumably deal

ing with a small area of necrosis surrounded by a large zone of ischemia The work of Prinzmetal and his associates has demonstrated that the absence of characteristic electrocardiographic changes indicative of infarction means only that the subepicardial region of the heart has been undamaged Since it is the endocardial surface of the myocardium that is more likely to be involved in a small infarct it is not surprising that confirmatory electrocardiographic proof of the infarction is usually wanting The authors think it probable that when these attacks occur out of the blue a partial or even complete closure of a coronary branch has taken place and that the collateral blood supply to the involved area maintains a tenuous balance between supply and need

Preinfarctional angina is the most dangerous type of coronary disease because the patient faces not only the hazard of repeated severe anginal attacks but in most instances the additional hazard of a forthcoming myocardial infarction Thus measures to minimize the size of such an infarct are urgently indicated and frequently appear to be successful The patient s activity should be restricted to the quiet of a hospital room Heparin should be administered for several weeks or longer in dosage adequate to produce the desired anticoagulant effect and also because of its action on the lipoproteins A low fat low caloric diet with frequent small feedings should be instituted Nitroglycerin ointment should be spread thinly on the skin every 3 to 4 hr in dosage sufficient to prevent anginal attacks and sublingual tablets used to treat the pain if it should occur

Myocardial Infarction

Although partial descriptions of the clinical picture of this disorder had appeared in the literature from time to time for many years it was not until the clear discussions of James B Herrick in 1912 and 1919 that the condition began to be recognized generally

The terms *coronary occlusion coronary thrombosis* and *myocardial infarction* are often used synonymously Actually coronary occlusion may be the result of embolism or more commonly may be the consequence of gradual arteriosclerotic narrowing without actual thrombosis Coronary occlusion with or without thrombosis may lead to infarction when the occlusion develops rapidly and may be associated with no infarction when the process is slow Gradual progressive narrowing of coronary vessels resulting in partial occlusion may be associated with anginal attacks of progressively increasing severity and duration (p 1264) and such attacks may persist over a period of several weeks without the development of myocardial infarction if an adequate collateral circulation develops and terminates the attacks Under certain circumstances such as prolonged paroxysmal tachycardia myocardial infarction may develop without actual structural occlusion of the coronary vessels Such considerations make it clear that the interrelationship between coronary occlusion coronary thrombosis and myocardial infarction is not simple Actually coronary thrombosis and coronary occlusion are often recognizable only by post mortem examination On the other hand myocardial infarction produces a characteristic clinical picture which will usually lead readily to the correct diagnosis

Etiology The etiologic factors concerned are essentially those already discussed in regard to coronary arteriosclerosis and angina pectoris The fundamental pathologic process in the great majority of instances is an atheromatous change and myocardial infarction may result from gradual narrowing of the lumen due to such atheromatosis or from the development of a blood clot at the site of the atheroma A less common cause of acute myocardial infarction is a subendothelial hemorrhage in the wall of a coronary vessel Among the rarer causes of myocardial infarction are periarteritis and occlusion of a coronary o tium by luetic aortitis or dissecting aneurysm

Clinical Picture The patient is seized with a *chest pain similar to that of angina* except that *it is unrelated to exertion* It is more intense and prolonged tends to radiate more widely and is not influenced by nitroglycerin The pain usually is described as having a constrictive quality it tends to reach a peak rapidly and it remains at this level without wavering from moment to moment in other words *it is a steady pain not affected by bodily movements or breathing or swallowing—an extremely important diagnostic feature* Shortly after the onset of the pain the patient becomes dyspneic weak and faint nausea and vomiting are common At this time the skin is pallid cool and moist and the blood pressure is considerably lower than the previous levels In milder cases the blood pressure during the first half hour of the attack may be higher than prior levels The heart rate is increased to 100 to 120 the sounds are faint a gallop rhythm is frequently heard and fine and medium moist rales are audible at the bases of the lungs After a variable period of time the manifestations of shock disappear and the pain gradually subsides leaving behind a dull ache that may persist up to a day or so Within a few hours after the beginning of the pain leukocytosis and increased transaminase levels followed by fever are observed still later usually some time between 24 and 48 hr after the onset the sedimentation rate becomes elevated In severe instances the white blood count rises to 12 000 to 20 000 and remains elevated for about 10 to 14 days the fever reaches levels of 100 to 103 F and

subsides in about 7 to 10 days the sedimentation rate is increased for 3 or 4 weeks In about 80 per cent of the cases alterations in the electrocardiogram characteristic of myocardial infarction are noted from the onset of the attack S T elevations followed by inversion of the T waves and the appearance of Q waves In the remainder of the cases the electrocardiographic abnormalities absent in the first day or two are usually observed within 7 to 10 days when daily tracings are made and in a small minority only minor and nonspecific abnormalities are noted even in the presence of an otherwise classical clinical picture

After the first day or two when the pain has usually disappeared the patient may be so free of subjective symptoms that it may be difficult to persuade him of the seriousness of the attack and *of the necessity of several weeks of careful management* The gallop rhythm and the basilar rales may persist for as long as 2 or 3 weeks Some time during the first week usually after the first day and before the seventh a pericardial friction rub may be heard in about 10 to 15 per cent of the cases The pericarditis is usually asymptomatic

The above description applies to patients suffering an attack of moderate severity In patients with milder attacks there may be few or no manifestations of forward or backward failure and the evidence of myocardial necrosis (leukocytosis fever and elevated sedimentation rate) may be correspondingly inconspicuous Almost invariably however at some time during the first week some slight increase in the white cell count or temperature or sedimentation rate may be noted provided the appropriate observations are made sufficiently frequently

In the most severe cases all the symptoms described in the typical case are intensified Forward failure is profound and the patient remains in a state of shock for a number of hours or even days death being prevented only by the vigorous administration of pressor amines At the same time backward failure in the form of pulmonary edema and later systemic congestive failure are more pronounced

The severity of the attack is judged not by the extent of the electrocardiographic alterations but by the clinical picture and the evidence of myocardial necrosis The more severe the clinical manifestations of shock and congestive failure the higher and longer the duration of fever leukocytosis transaminase and sedimentation rate elevation the greater has been the myocardial damage regardless of the appearance of the electrocardiogram The converse is also true when all the above phenomena are minimal the myocardial insult has been small even in the face of an electrocardiographic appearance of "massive infarction (Q waves and absent R waves across the entire precordium) The electrocardiogram is invaluable in substantiating a clinical impression of acute myocardial infarction it is of little value in informing as to the gravity of the attack

In some patients the infarction may be painless It is impossible to state the percentage of patients in whom a painless infarct develops since in some a routine electrocardiogram may reveal the characteristic pattern of infarction without any corresponding history in the past In these persons the myocardial necrosis and repair have proceeded so silently as to have never caused any discomfort of which even an alert person was aware In others the symptoms were so mild that the patient never considered it necessary to consult a physician In still others the classical picture minus the pain may be witnessed sudden development of symptoms and signs of forward and backward failure with shock pulmonary edema electrocardiographic abnormalities etc When pain is absent or atypical and when electrocardiographic changes are minimal the diagnosis may be obscure Especially confusing are those exceptional instances in which the decline in blood pressure may lead to focal neurologic disturbances such as convulsions or hemiplegia These disturbances may dominate the picture myocardial infarction being overlooked In most of the cases of acute painless infarction however the initial symptom is severe dyspnea sometimes associated with acute pulmonary edema

Complications In enumerating the untoward events responsible for practically all deaths in acute myocardial infarction no attempt will be made to differentiate between those occurrences that are more accurately considered inherent consequences of the primary disorder and those that should be strictly designated as complications When the former reach a certain degree of intensity they introduce special problems of management

Shock When at the onset of the attack the systolic level falls below 80 to 90 mm Hg in a previously normotensive person or below 110 to 120 mm Hg in a previously hypertensive patient and remains at these low levels for 2 hr or more and when this fall is associated with the clinical picture of shock—skin pale and drenched in sweat profound weakness clouding of the sensorium peripheral arterial pulsations impalpable—the prognosis is extremely grave over 90 per cent ending in death The cause of the shock is not fully understood a major factor must be the sudden drop in cardiac output Whether in addition obscure reflexes play a contributing role is not known Even if the patient survives this period of shock serious complications resulting from the prolonged hypotension and peripheral vasoconstriction may ensue acute tubular necrosis of the kidneys focal cerebral disorders

gangrene of the skin and muscle in the extremities and further extension of the infarcted area in the myocardium

Acute Pulmonary Edema In the earliest stages of a severe attack the sudden impairment of contractile power of the left ventricle may lead to serious or fatal pulmonary edema This is usually associated with more or less severe shock signs of systemic congestive failure are absent If the patient survives for more than a day or two and left ventricular contractile power fails to recover or if he has practically recovered and a complication supervenes that imposes an additional burden on the left ventricle (ruptured septum new infarction ectopic tachycardia etc) the picture of systemic congestive failure appears

Abnormal Rhythms The appearance of an ectopic tachycardia which may be of any type may suddenly alter the course from one that is progressing favorably to one of grave danger The harmful effect of these arrhythmias is due to the rapid rate and the resulting abbreviation of diastole Ventricular tachycardia presents an additional danger since it is the forerunner of fatal ventricular fibrillation Heart block of either second or third degree introduces the risk of ventricular standstill or fibrillation

Rupture of the Myocardium Rupture of the free wall of the ventricle at the site of the infarction with rapid development of cardiac tamponade occurs in about 10 per cent of the fatal cases This is apt to develop during the first 14 days and death occurs so rapidly that it is rarely possible to determine which of the causes of sudden death has been responsible Rupture of the interventricular septum is much less common The diagnosis is suggested by the appearance of a loud systolic murmur at the lower left sternal border often associated with a systolic thrill the rapid increase in congestive failure and death within a week Rarely a patient with this complication may live for several years Far more uncommon than either of the above forms of rupture is the rupture of an infarcted papillary muscle which is responsible for the sudden appearance of murmurs loudest at the apex and the development of fatal pulmonary edema within a few hours

Thromboembolism Systemic embolism arising from left ventricular mural thrombi may lead to serious or fatal complications gangrene of legs hemiplegia occlusion of abdominal vessels etc Much more common are pulmonary emboli sometimes due to a right ventricular mural thrombus overlying a septal infarct but far more often due to emboli originating in the deep veins of the legs Finally a second myocardial infarct due to development of another coronary thrombosis may occur while the patient is recovering from the first

Prognosis In this condition as in angina pectoris *prognosis is always uncertain There is perhaps no* other disorder in which a patient apparently pro*gressing favorably is so likely to die unexpectedly* Likewise there are few conditions in which a patient so seemingly moribund may recover to assume eventually a life of relatively normal activity In general the prognosis is better in middle-aged than in elderly patients because the younger individuals are less apt to have advanced sclerotic changes throughout the coronary tree and perhaps especially because the older patients are more apt to have serious concurrent disease such as latent senile heart disease prostatic enlargement emphysema etc The prognosis is likely to be better when the infarction sets in suddenly than when it is preceded by prolonged and severe attacks of angina pectoris (p 1264) The appearance of severe con*gestive failure adds to the gravity of the outlook as does persistence of the pain beyond a period of 1 or 2 days*

Frequent ventricular premature beats sometimes precede the development of ventricular tachycardia and hence should be viewed as an unfavorable sign particularly if they do not disappear on administration of quinidine The gravity of prolonged shock severe pulmonary edema and the various ectopic tachycardias has already been mentioned The outlook when these rapid rhythms supervene depends on the promptness with which they can be terminated The danger with ventricular tachycardia arises from the fact that even after one paroxysm has been stopped another may start and progress to fatal ventricular fibrillation or cause death by myocardial failure despite the use of quinidine in the usual prophylactic doses In general if the patient has surmounted the initial insult to the myocardium with its attendant shock and pulmonary edema and has survived beyond 14 days when myocardial rupture and ectopic rhythms are most likely to occur the chief risk is the development of a thromboembolic complication At no time however is the risk of sudden death due to ventricular standstill or fibrillation absent

Treatment The first principle is that the treatment should be directed at the patient rather than at the electrocardiogram This is especially important in the decisions concerning activity and return to work

During the first few hours complete rest is indicated and sufficient opiates or other analgesics should be used to relieve the pain Food may be restricted to fruit juices for the first 24 to 48 hr and water given in amounts of 1 000 to 1 500 ml or more depending on the extent of the loss by sweating Enough fluids should be given to ensure a urinary output of at least 700 ml The intravenous route for administration of fluids and drugs should be avoided except when imperative

If there are numerous rales in the lungs or if cyanosis is present oxygen is urgently needed Even in the absence of these signs oxygen is probably of value as the elevation of arterial oxygen content although small in degree will allow a given level of tissue oxygen tension to be achieved at a lower level of cardiac output and may therefore rest the heart It has been demonstrated in animals that the oxygen content of the marginal areas around the infarct is increased by the administration of oxygen

Opinions differ concerning the value of the use of coronary dilator drugs during the acute phase There is experimental evidence against the value of theophylline derivatives (aminophylline) which have been shown to increase cardiac work more than coronary flow The clinical evidence for the use of atropine and papaverine is not convincing Theoretically drugs which dilate the coronary arteries without causing significant decline in blood pressure would be expected to be beneficial

There is evidence now disputed that anticoagulant therapy may be of great value in the management of patients with myocardial infarction The purposes of such therapy are to prevent phlebothrombosis and hence reduce the likelihood of pulmonary embolism and infarction to prevent further thrombosis in the coronary vessels and to prevent mural thrombosis

Anticoagulant therapy may increase the gravity of cerebral or other embolisms and there is evidence that hemopericardium with or without rupture of the myocardium is about twice as frequent when Dicumarol is employed It is generally agreed that anticoagulant therapy should be used in the severer forms of myocardial infarction but there is conflicting opinion about the advisability of its use in the milder (good risk) forms Nevertheless it is difficult to ignore the possibility that even in a good risk patient an embolus from a mural thrombus may be catastrophic When Dicumarol or some similar drug affecting the prothrombin content of the blood is employed reliable laboratory control is essential and vitamin K_1 (Mephyton) should always be immediately available if hemorrhage or dangerous prolongation of prothrombin time occurs These drugs are contraindicated when significant disease of the liver or kidney or a recently bleeding ulcerative lesion is present

Heparin is usually employed only during the first 2 to 3 days until the prothrombin time has been increased to therapeutic levels It is ordinarily not used as the sole anticoagulant agent because parenteral injection is required and also because of its expense Nevertheless the authors believe there are sound reasons for using heparin exclusively The administration of aqueous heparin intravenously or with a small amount of procaine subcutaneously with a very small caliber needle is practically painless The expense of the heparin is largely offset by the avoidance of the daily prothrombin time estimation necessitated when Dicumarol is used since a fairly constant elevation of the coagulation time to therapeutic levels can be maintained once the proper dose of heparin has been ascertained The antithrombin effect of heparin is greater and more reliable as an anticoagulant than is the antiprothrombin effect of Dicumarol Should bleeding occur or the coagulation time be raised excessively protamine sulfate has an almost immediate neutralizing effect Finally there is evidence that heparin exerts a beneficial effect in coronary disease aside from its capacity to prolong coagulation time

Aqueous heparin should be given every 8 hr in an amount sufficient to increase the coagulation time to three to four times the pretreatment level The usual dose is 40 to 100 mg Depot heparin should not be employed since absorption is too irregular to give reliable results

After the initial stage has passed and the pain has ceased the problem of therapy changes somewhat The diet should be low in sodium low in calories (800 to 1000 cal) low in cholesterol and generous in ascorbic acid which may perhaps have a favorable effect on the healing of the infarct Pending more complete knowledge it would seem wise to administer ascorbic acid in oral doses of about 300 mg per day for the first 3 weeks

One of the major problems in the management of patients with myocardial infarction involves the decision concerning the duration and rigidity of restriction of activity There should be no fixed rules the program depending on the severity of the illness and to a lesser degree on the temperament of the patient Ordinarily the semirecumbent posture will be preferable when there is slight dyspnea the sitting position when dyspnea is marked and the recumbent position when dyspnea is absent or a shock like state exists Some physicians still advocate rest in bed for a period of several weeks but others including the writers believe that patients should be allowed to sit up in bed as soon as the shock and pain have disappeared and should be allowed to sit in a chair within the next few days It is probable although the evidence is incomplete that there is every advantage in prolonged restriction of activity but no advantage in prolonged rigid rest in bed The question whether the patient should use the bedpan or be allowed to walk to the toilet can usually be answered by adopting the middle course of a bedside commode when the use of the bedpan is attended by discomfort

In order to avoid straining at stool, Colace or Velmol or a mineral oil emulsion should be employed

Mild sedatives of the barbiturate group or reserpine are likely to be useful The latter may be preferable since it may effect a desirable slowing of the heart rate and also a *reduction* of blood pressure in hypertensive patients

During the period of bed rest *it is important that the legs be massaged and that first passive and later active movement be initiated* in order to minimize the likelihood of phlebothrombosis Elastic stockings are also useful in this respect

The discussion thus far has been centered on the management of the milder instances without the more serious complications The latter may now be considered

Treatment of Congestive Failure Congestive failure usually takes the form of pulmonary edema (Chap 226) Intravenous Cedilanid is the procedure of choice The drug is best administered as a slow infusion in glucose solution The usual initial dose for patients not previously receiving digitalis is 1 0 to 2 0 mg administered during a period of 6 to 10 hr while the patient is constantly observed for the appearance of arrhythmias or nausea which was not previously present Once congestive failure is controlled maintenance doses of 0 2 to 0 3 mg Cedilanid can be given twice daily parenterally for a few days After this period one can change to the oral administration of a long acting preparation such as Digitoxin or powdered leaf Because of the rapid excretion of Cedilanid the initial total daily dose of the longer acting preparations will usually need to be about 0 4 mg (*Digitoxin*) or 0 4 Gm (powdered leaf) for 2 to 4 days Then a daily maintenance dose one quarter to one half as great may be administered (p 1311)

The other procedures to be used in the management of congestive failure are discussed in Chap 226

Shock This is a grave complication The signs of forward failure and backward failure (Chap 14) usually coexist Digitalis should be administered as described At the same time vasoconstrictor drugs should be employed as indicated in Chap 271 These too should be administered by slow intravenous drip and should be discontinued if ectopic rhythms including numerous ventricular premature beats develop Norepinephrine is a reliable preparation The dose varies markedly from patient to patient and should usually be administered according to the rate required to maintain a pulse pressure and a systolic pressure of at least 30 and 100 ml Hg respectively (Chap 271) However aside from the level of blood pressure the other signs of shock are important Indeed a well marked lowering of blood pressure even to values as low as 95/65 which is not associated with clammy skin ashen color apathy or lassitude usually requires no treatment

Other procedures such as infusions of blood plasma or salt solution are probably more apt to be harmful than beneficial Some patients with severe forward failure will die despite the use of digitalis and norepinephrine but other seemingly moribund patients will recover

Arrhythmias These frequently occur and should be managed as discussed in the preceding chapter When the disturbances of rhythm occur in a patient with myocardial infarction they are more hazardous and often more difficult to control than under other circumstances Nevertheless they often respond dramatically to treatment which may be lifesaving in such patients

Thromboembolic Episodes These should be prevented by the use of anticoagulants massage of the legs passive and active movements elastic bandages and getting the patient out of bed and into a chair as already indicated When in spite of these precautions pulmonary infarction occurs the question of venous ligation should be entertained (Chap 236)

Rupture of the Heart Transmural rupture is not infrequent during the first 2 weeks but is rare thereafter It may occur during straining at stool Possibly the liberal use of vitamin C tends to prevent it Rupture of a papillary muscle or of the interventricular septum is rare These complications are *not amenable to therapy*

Secondary Skeletal Pain This is common not only in the shoulder arm and hand but also in the pectoral muscles (Chap 4) This type of pain while not of serious physical significance is likely to induce grave anxiety the patient fearing that another heart attack" has occurred Reassurance massage heat and acetylsalicylic acid are valuable When the pain is severe stellate ganglion block or cortisone may produce dramatic relief

Secondary Anxiety States Emphasis has been directed repeatedly at the importance of psychologic management in all cases of disorders of the heart In none are sympathetic understanding and insight into the emotional problems of the patient more necessary than when dealing with individuals who have suffered a myocardial infarct Most of these patients are stricken at the height of their business or professional careers and of their responsibility to family and colleagues The ominous significance of heart attack" and "coronary thrombosis" has attained such wide diffusion among the laity especially through reports of the unexpected deaths of friends who but a few days before had seemed robust and well that hardly anyone who has sustained such an attack can fail to ponder anxiously on what the future will hold for him Aside from the immediate threat to his life the questions of his capacity to carry on his business job or profession and of the far reaching influence this ill

If there are numerous rales in the lungs or if cyanosis is present oxygen is urgently needed Even in the absence of these signs oxygen is probably of value as the elevation of arterial oxygen content although small in degree will allow a given level of tissue oxygen tension to be achieved at a lower level of cardiac output and may therefore rest the heart It has been demonstrated in animals that the oxygen content of the marginal areas around the infarct is increased by the administration of oxygen

Opinions differ concerning the value of the use of coronary dilator drugs during the acute phase There is experimental evidence against the value of theophylline derivatives (aminophylline) which have been shown to increase cardiac work more than coronary flow The clinical evidence for the use of atropine and papaverine is not convincing Theoretically drugs which dilate the coronary arteries without causing significant decline in blood pressure would be expected to be beneficial

There is evidence now disputed that anticoagulant therapy may be of great value in the management of patients with myocardial infarction The purposes of such therapy are to prevent phlebothrombosis and hence reduce the likelihood of pulmonary embolism and infarction to prevent further thrombosis in the coronary vessels and to prevent mural thrombosis

Anticoagulant therapy may increase the gravity of cerebral or other embolisms and there is evidence that hemopericardium with or without rupture of the myocardium is about twice as frequent when Dicumarol is employed It is generally agreed that anticoagulant therapy should be used in the severer forms of myocardial infarction but there is conflicting opinion about the advisability of its use in the milder (good risk) forms Nevertheless it is difficult to ignore the possibility that even in a good risk patient an embolus from a mural thrombus may be catastrophic When Dicumarol or some similar drug affecting the prothrombin content of the blood is employed reliable laboratory control is essential and vitamin K_1 (Mephyton) should always be immediately available if hemorrhage or dangerous prolongation of prothrombin time occurs These drugs are contraindicated when significant disease of the liver or kidney or a recently bleeding ulcerative lesion is present

Heparin is usually employed only during the first 2 to 3 days until the prothrombin time has been increased to therapeutic levels It is ordinarily not used as the sole anticoagulant agent because parenteral injection is required and also because of its expense Nevertheless the authors believe there are sound reasons for using heparin exclusively The administration of aqueous heparin intravenously or with a small amount of procaine subcutaneously with a very small caliber needle is practically painless The expense of the heparin is largely offset by the avoidance of the daily prothrombin time estimation necessitated when Dicumarol is used since a fairly constant elevation of the coagulation time to therapeutic levels can be maintained once the proper dose of heparin has been ascertained The antithrombin effect of heparin is greater and more reliable as an anticoagulant than is the antiprothrombin effect of Dicumarol Should bleeding occur or the coagulation time be raised excessively protamine sulfate has an almost immediate neutralizing effect Finally there is evidence that heparin exerts a beneficial effect in coronary disease aside from its capacity to prolong coagulation time

Aqueous heparin should be given every 8 hr in an amount sufficient to increase the coagulation time to three to four times the pretreatment level *The usual dose is 40 to 100* mg Depot heparin should not be employed since absorption is too irregular to give reliable results

After the initial stage has passed and the pain has ceased the problem of therapy changes somewhat *The diet should* be low in sodium low in calories (800 to 1000 cal) low in cholesterol and generous in ascorbic acid which may perhaps have a favorable effect on the healing of the infarct Pending more complete knowledge it would seem wise to administer ascorbic acid in oral doses of about 300 mg per day for the first 3 weeks

One of the major problems in the management of patients with myocardial infarction involves the decision concerning the duration and rigidity of restriction of activity There should be no fixed rules the program depending on the severity of the illness and to a lesser degree on the temperament of the patient Ordinarily the semirecumbent posture will be preferable when there is slight dyspnea the sitting position when dyspnea is marked and the recumbent position when dyspnea is absent or a shock like state exists Some physicians still advocate rest in bed for a period of several weeks but others including the writers believe that patients should be allowed to sit up in bed as soon as the shock and pain have disappeared and should be allowed to sit in a chair within the next few days It is probable although the evidence is incomplete that there is every advantage in prolonged restriction of activity but no advantage in prolonged rigid rest in bed The question whether the patient should use the bedpan or be allowed to walk to the toilet can usually be answered by adopting the middle course of a bedside commode when the use of the bedpan is attended by discomfort

In order to avoid straining at stool, Colace or Velmol or a mineral oil emulsion should be employed

manly on the left ventricle left sided failure with rise in pressure in the left atrium and consequent pulmonary engorgement may set in suddenly and produce attacks of paroxysmal nocturnal dyspnea or of acute pulmonary edema These attacks may appear as the first manifestation of congestive failure more frequently they occur after appreciable exertional dyspnea has become evident Gallop rhythm and pulsus alternans are observed with especial frequency and when they occur they are ominous signs for they indicate not merely disease but impending or actual myocardial failure Eventually provided the patient does not succumb to an attack of acute pulmonary edema left ventricular failure is followed by failure of the right ventricle and the complete picture of congestive failure is apparent

Treatment The treatment of hypertensive heart disease consists essentially of the treatment of the hypertension plus the management of congestive failure (Chap 226) or of angina pectoris (p 1262) according to which of these conditions exists The increasingly favorable results from the use of antihypertensive drugs (Chap 227) make it likely that cardiac complications may be prevented more effectively in the future than in the past

COR PULMONALE

Although pulmonary hypertension with eventual right ventricular failure may follow any type of left sided heart failure as well as certain congenital lesions the term *cor pulmonale* is applied only to those instances in which the primary cause of pulmonary hypertension is disease of the lungs or of the pulmonary vessels Such a sequence of events may set in acutely following pulmonary embolism of sufficient grade to cause serious interference with the circulation through the lungs The subacute type which endures for a few weeks to a few months may be due to recurrent embolism including that from amniotic fluid extensive miliary carcinomatosis or to any rapidly progressive and widespread infection of the lungs as by miliary tuberculosis or by pyogenic or fungous disease However the usual and the most important type is chronic cor pulmonale

The most common causes of chronic cor pulmonale are emphysema asthma and bronchiectasis which frequently appear in combination with one another Other causes include pneumoconiosis pulmonary fibrosis due to any extensive chronic infection kyphoscoliosis sarcoidosis beryllium granulomatosis and other granulomatoses of undetermined etiology scleroderma schistosomiasis essential pulmonary hypertension Ayerza's disease ("black cardiac") originally ascribed to syphilitic disease of the pulmonary arteries is like the proverbial ghost that is never seen except in a book or by someone else This term if used at all should be applied to the patient with cor pulmonale polycythemia and a severe form of pulmonary insufficiency

Diagnosis Cor pulmonale should be suspected in any individual presenting evidence of any of the above etiologic factors who also reveals signs of right ventricular hypertrophy The dyspnea in these patients is of the pulmonary rather than the cardiac type (Chap 226) and is often relatively slight in the resting state as compared with such prominent manifestations of right ventricular failure as distention of the veins and enlargement of the liver A few of the patients with chronic cor pulmonale have substernal pain almost but not quite identical with the pain of angina pectoris Occasionally syncope on exertion occurs The signs indicative of right ventricular hypertrophy are the systolic lift over the body of the heart the increased second pulmonic sound and the roentgenologic evidence of enlargement of the pulmonary artery and its main branches and of the right ventricle Electocardiographic evidence of right ventricular hypertrophy is a late phenomenon and its absence does not exclude cor pulmonale Cyanosis polycythemia and clubbing of the fingers signify the presence of long acting arterial hypoxemia Clubbing alone may be due to bronchiectasis Hydrothorax is rare in failure due to uncomplicated cor pulmonale The arm to lung (ether) circulation time may be prolonged but the lung to tongue (Decholin minus ether) time is usually normal This is the reverse of the situation when dyspnea is of cardiac origin

Pathologic Physiology The basic fault in chronic cor pulmonale is the pulmonary hypertension caused by the reduction in the size and distensibility of the pulmonary vascular bed When this is due solely to irreversible lesions in or about the pulmonary vessels the sequence of events is relatively simple With the progress of the fundamental disorder pulmonary hypertension present at first only with an increase in pulmonary blood flow due to exercise or fever gradually increases until it is constantly present and later hypertrophy and dilation and finally failure of the right ventricle occur End-diastolic pressure rises cardiac output declines systemic congestive failure appears and from this point on rapid progression to death ordinarily ensues

When anatomic restriction of the pulmonary bed is relatively slight but is associated with arterial hypoxemia (saturation less than 85 per cent) that may be caused by a variety of mechanisms—hypoventilation impairment of diffusion venoarterial shunts uneven ventilation in relation to blood flow—the situation becomes more complicated Severe hypoxemia is associated with carbon dioxide re

ness will have on the lives of his wife and children must obtrude on his thoughts It is not necessary to discuss the innumerable anxieties that inevitably attend the convalescence of the person who lies in bed or leads the restricted life following the acute attack Suffice it to say that these ideas do pre occupy a large part of his thoughts and recognition of their existence must not be overlooked by the physician however impassive and philosophic the patient may seem to be It is during these days that the *physician must exert his utmost skill in* restoring confidence in explaining in simple terms the significance of the illness and in allaying fears and anxieties The task is not easy for the physician cannot forget that behind the apprehensions of the patient there is a core of truth that can never be dissipated He can however come to a reasonably accurate estimate as to the degree of activity in which the patient may ultimately participate and he can within the limitations imposed by a malady of such uncertain course encourage a life that will often be more active and useful than the patient had imagined He can point out the many useful and productive years that others suffering from the same disorder have experienced The details and the intricacies of this problem will be as varied as the temperaments and the circumstances sur rounding each individual patient The administra tion of drugs and the supervision of strictly medical measures constitute a progressively diminishing part of the total management as the days of the acute attack recede and the days of convalescence and resumption of more or less normal life progress

The question arises as to how soon a patient should resume his work after a myocardial infarc tion The answer should never be based on the electrocardiogram alone but rather on the total clinical picture the severity of the attack and the rate and completeness of recovery as well as the nature of the patient s occupation There can be no rigid rules Certainly the patient who has sustained a relatively small infarction as judged by the ab sence of shock and myocardial failure and the pres ence of minimal electrocardiographic alterations fever leukocytosis and elevation of sedimentation rate should be managed altogether differently from the person in whom all these data have indicated an extensive area of necrosis Consequently some individuals may logically be permitted to return to work within 4 to 6 weeks after the onset of the attack Others may require many weeks or months or may never be able to work again particularly when the occupation is one in which strenuous physical exertion is unavoidable In all cases the return to work should be gradual and full activity assumed only under careful and frequent observa tion Most patients will benefit by a permanent plan of a noon rest period of 1 hr Activities which in duce tension fatigue dyspnea or anginal pain should be permanently forbidden

Smoking in moderation (8 to 12 cigarettes daily) may be allowed in most instances but should be forbidden to those patients who develop pain un due rise in blood pressure tachycardia or prema ture beats following smoking The possible value of the ballistocardiogram as a guide to the harmful effects of smoking has already been mentioned There is no evidence that alcohol in moderation *i e 1 to 3 oz of whisky per day is harmful and* none that it is beneficial other than through its sedative action

The diet employed for patients with angina pec toris should be followed permanently by patients who have recovered from an acute myocardial in farction

HYPERTENSIVE HEART DISEASE

The discussion to follow will deal not with the question of hypertension in general which will be discussed in Chap 227 but only with heart disease resulting from hypertension

Elevation of blood pressure is the most common cause of congestive heart failure among patients in the forty to fifty five year age group it accounts for a minority of the instances under the age of forty and when coupled with senile change is fre quently an important factor in the production of congestive failure in patients in the seventh and eighth decades About one half the individuals with hypertension will eventually develop congestive failure although this complication usually does not occur for many years

Hypertension is also an important etiologic factor in relation to angina pectoris (p 1261)

Hypertensive heart disease is that form of heart disease that is associated with long continued in creased arteriolar resistance and is presumably due largely if not entirely to the increased work of the left ventricle contracting against a permanently increased peripheral resistance

A sustained increase in the blood pressure usually leads to left ventricular hypertrophy (p 1234) in some cases so slight as to be clinically undetectable and insignificant This is often the sole manifesta tion of early hypertensive heart disease

Clinical Course Following the discovery of the hypertension a number of years may elapse 10 or 20 or even 30 before symptoms referable to the heart develop if they develop at all This may be true even though levels as high as 240 systolic and 120 diastolic have been obtained during a large part of this time In some the clinical picture is that of coronary disease angina pectoris or myo cardial infarction In others a much larger group congestive failure ensues Because the strain is pri

mainly on the left ventricle left sided failure with rise in pressure in the left atrium and consequent pulmonary engorgement may set in suddenly and produce attacks of paroxysmal nocturnal dyspnea or of acute pulmonary edema. These attacks may appear as the first manifestation of congestive failure more frequently they occur after appreciable exertional dyspnea has become evident Gallop rhythm and pulsus alternans are observed with especial frequency and when they occur they are ominous signs for they indicate not merely disease but impending or actual myocardial failure Eventually provided the patient does not succumb to an attack of acute pulmonary edema left ventricular failure is followed by failure of the right ventricle and the complete picture of congestive failure is apparent.

Treatment The treatment of hypertensive heart disease consists essentially of the treatment of the hypertension plus the management of congestive failure (Chap 226) or of angina pectoris (p 1262) according to which of these conditions exists The increasingly favorable results from the use of antihypertensive drugs (Chap 227) make it likely that cardiac complications may be prevented more effectively in the future than in the past.

COR PULMONALE

Although pulmonary hypertension with eventual right ventricular failure may follow any type of left sided heart failure as well as certain congenital lesions the term *cor pulmonale* is applied only to those instances in which the primary cause of pulmonary hypertension is disease of the lungs or of the pulmonary vessels Such a sequence of events may set in acutely following pulmonary embolism of sufficient grade to cause serious interference with the circulation through the lungs The subacute type which endures for a few weeks to a few months may be due to recurrent embolism including that from amniotic fluid extensive miliary carcinomatosis or to any rapidly progressive and widespread infection of the lungs as by miliary tuberculosis or by pyogenic or fungous disease However the usual and the most important type is chronic cor pulmonale

The most common causes of chronic cor pulmonale are emphysema asthma and bronchiectasis which frequently appear in combination with one another Other causes include pneumoconiosis pulmonary fibrosis due to any extensive chronic infection kyphoscoliosis sarcoidosis beryllium granulomatosis and other granulomatoses of undetermined etiology scleroderma schistosomiasis essential pulmonary hypertension Ayerza's disease ("black cardiac") originally ascribed to syphilitic disease of the pulmonary arteries is like the proverbial ghost that is never seen except in a book or by someone else This term if used at all, should be applied to the patient with cor pulmonale polycythemia and a severe form of pulmonary insufficiency

Diagnosis Cor pulmonale should be suspected in any individual presenting evidence of any of the above etiologic factors who also reveals signs of right ventricular hypertrophy The dyspnea in these patients is of the pulmonary rather than the cardiac type (Chap 226) and is often relatively slight in the resting state as compared with such prominent manifestations of right ventricular failure as distention of the veins and enlargement of the liver A few of the patients with chronic cor pulmonale have substernal pain almost but not quite identical with the pain of angina pectoris Occasionally syncope on exertion occurs The signs indicative of right ventricular hypertrophy are the systolic lift over the body of the heart the increased second pulmonic sound and the roentgenologic evidence of enlargement of the pulmonary artery and its main branches and of the right ventricle Electocardiographic evidence of right ventricular hypertrophy is a late phenomenon, and its absence does not exclude cor pulmonale Cyanosis polycythemia and clubbing of the fingers signify the presence of long acting arterial hypoxemia Clubbing alone may be due to bronchiectasis Hydrothorax is rare in failure due to uncomplicated cor pulmonale The arm to-lung (ether) circulation time may be prolonged but the lung to-tongue (Decholin minus ether) time is usually normal This is the reverse of the situation when dyspnea is of cardiac origin

Pathologic Physiology The basic fault in chronic cor pulmonale is the pulmonary hypertension caused by the reduction in the size and distensibility of the pulmonary vascular bed When this is due solely to irreversible lesions in or about the pulmonary vessels the sequence of events is relatively simple With the progress of the fundamental disorder pulmonary hypertension present at first only with an increase in pulmonary blood flow due to exercise or fever gradually increases until it is constantly present, and later hypertrophy and dilation and finally failure of the right ventricle occur End-diastolic pressure rises cardiac output declines systemic congestive failure appears and from this point on rapid progression to death ordinarily ensues

When anatomic restriction of the pulmonary bed is relatively slight but is associated with arterial hypoxemia (saturation less than 85 per cent) that may be caused by a variety of mechanisms—hypoventilation impairment of diffusion venoarterial shunts uneven ventilation in relation to blood flow—the situation becomes more complicated Severe hypoxemia is associated with carbon dioxide re

tention and respiratory acidosis The hypoxia increases the already existent but mild pulmonary hypertension and this effect is further enhanced by the increased cardiac output secondary to the hypoxia Hypoxia also stimulates the production of red blood cells blood volume and viscosity increase and both aggravate pulmonary hypertension still further Right ventricular dilatation and hypertrophy and eventually failure take place primarily because of the pulmonary hypertension but also because of the increased cardiac output and possibly through a direct effect of hypoxia on the myocardium Cardiac output declines but may still be above the normal level plasma volume increases and one more straw is added to the already numerous burdens overwhelming the pulmonary circulation and right ventricle

Prognosis Prognosis in cor pulmonale depends on how many and how effectively the reversible factors contributing to pulmonary hypertension can be influenced Pure fibrosis with extensive and irreversible vascular lesions and essential pulmonary hypertension represents one extreme of a spectrum whereas uncomplicated chronic obstructive emphysema exemplifying a type of disorder largely dependent on functional and ameliorable derangements represents the other and more favorable end of the spectrum of respiratory disorders leading to cor pulmonale There are all gradations between

Treatment The acute development of failure in cor pulmonale due to emphysema is usually brought on by some new pulmonary disorder that diminishes an already compromised respiratory reserve A reasonably tolerable situation may be quickly converted into one of grave urgency The precipitating factor is usually an acute respiratory infection though it may be a pulmonary infarction or passive congestion of the lungs due to an unrelated cardiac disorder *The immediate obligation is to improve respiratory function and relieve hypoxia* The following general principles are important

1 *Avoidance of drugs that depress the respiratory center* The patient is often very restless and in distress Nevertheless morphine codeine and related drugs should be prohibited even barbiturates should be used with caution or avoided and sedation should be accomplished with chloral hydrate paraldehyde or one of the tranquilizing drugs

2 *Treatment of infection* Vigorous treatment of even mild acute infections should be instituted promptly by the administration of large doses of penicillin or other antibiotics depending on sputum culture and appropriate sensitivity tests

3 *Measures to facilitate ventilation* Steam inhalations and expectorants such as potassium iodide (15 drops of the saturated solution t i d) are valuable Bronchodilator drugs are extremely important

a Epinephrine 1 per cent or phenylephrine 1 per cent (Neo synephrine) or isopropyl norepinephrine 0 5 per cent (Isuprel) should be given as an aerosol either by a hand operated nebulizer or by a nebulizer attached to an oxygen tank the flow of oxygen being set at 6 or 7 liters per minute Five drops of one of these solutions is administered every 4 to 6 hr 1 drop of glycerin being added to minimize the feeling of dryness of the throat and the oxygen is bubbled through a column of water When the secretions are thick and tenacious the bronchodilator drug should be added to 1 0 ml Alevaire

b Aminophylline 0 25 to 0 5 Gm may be administered intravenously two to four times a day or since dehydration is often present by intravenous drip 0 5 Gm in 5 to 10 per cent glucose solution twice daily In many cases aminophylline 0 5 Gm by rectum either in a suppository or dissolved in 120 ml water is effective

c When wheezing is pronounced *cortisone* 100 mg t i d by mouth or corticotropin (ACTH) intramuscularly 40 mg daily in a slow acting form or 20 mg in a 5 to 10 per cent glucose solution drip may be extremely valuable in tiding the patient over the first few stormy days after which the dose should be tapered off to the minimal effective maintenance dose of cortisone Cortisone may also be given for sarcoidosis or other granulomatous lesions and a temporary improvement may be effected

d Mechanical respirators have been employed with great benefit in very ill patients in order to ensure adequate ventilation However the cost of the apparatus and the complexities involved in its use have thus far limited this procedure to a relatively few centers particularly interested in the problem

4 *Oxygen therapy* This should be used cautiously at first and then intermittently since when severe carbon dioxide retention has been present over a long period of time carbon dioxide narcosis may be induced sometimes suddenly when oxygen therapy is employed continuously

5 *Reduction of blood volume and viscosity by venesection* After the first 2 or 3 days this procedure should be instituted if the hematocrit is elevated 300 to 500 ml of blood being removed every 2 to 3 days until the hematocrit level is lowered to 45 to 50 per cent and provided the hemoglobin does not fall below 12 Gm

6 Therapy for congestive failure given alone is ineffectual with the therapeutic procedures described above rest digitalis low sodium diet and mercurial diuretics are of benefit

The various measures described above are employed with striking success when the problem is solely or largely chronic diffuse obstructive emphy

sema One is dealing with an illness of which one of the *most important components is a functional* derangement—hypoxia—that can be combated When recovery from the acute disorder has been obtained further therapy is that of the underlying emphysema For the patient with fibrosis or irremediable vascular disease little can be done beyond the usual procedures for congestive failure and *any* coincidental complications The outlook is dismal

SYPHILITIC HEART DISEASE

With rare exceptions syphilitic disorders of the heart are secondary to *involvement of the aorta* Syphilitic aortitis is discussed in Chap 229 and the discussion here is concerned only with such aspects as affect the heart directly These include the problems of angina pectoris and aortic insufficiency

Diagnosis Syphilitic aortic insufficiency should be suspected when a middle aged individual usually a male lacking a story of rheumatic fever presents the classic manifestations of aortic regurgitation *The suspicion is strengthened* when there is a history of a primary lesion or of antisyphilitic treatment in the past and when the serologic tests *for syphilis are positive (they are positive in about* 85 per cent of such cases) The tambour quality of the second heart sound at the aortic area is *often present but is also heard in patients with* aortic atheroma or hypertension Hence it is significant only when heard in a comparatively young *patient with a normal blood pressure*

Although syphilis does not produce deformity of the mitral valve the dilatation of the mitral ring *consequent to aortic regurgitation frequently causes* an apical systolic murmur Furthermore the Austin Flint murmur ("relative mitral stenosis) is frequently heard *in patients with syphilitic aortic re*gurgitation and this murmur cannot be differentiated with certainty from the similar murmur of mitral stenosis *Rough basal systolic murmurs are* commonly present and rarely a systolic thrill is felt but other evidence of aortic stenosis is not encountered *Hence the decision as to whether* in a given individual presenting aortic insufficiency there is syphilitic disease involving the aortic valve *only* or *rheumatic disease involving* either the aortic valve only or both the aortic and mitral valves cannot be made by auscultation alone The *presence of chronic auricular fibrillation constitutes* almost conclusive evidence that the lesion is rheumatic as does the presence of peripheral signs of *aortic stenosis or x ray evidence of* compression of the esophagus by an enlarged left atrium In the absence of such differential points the distinction *between syphilitic and rheumatic disease* has to be made on the basis of the history the serologic re*actions etc*

Clinical Course The clinical course of syphilitic aortic insufficiency is often rather rapid once symp*toms have begun to develop Many persons with this* disease develop acute left sided heart failure soon followed by evidence of right sided failure At first the usual methods of management for congestive failure are effective but within a year or two intractable heart failure tends to supervene The prognosis is not so grave as this in all instances but *in the majority of patients* the length of time from the onset of evidence of diminished cardiac reserve to intractable failure and death is shorter *than in most of the other types of chronic heart* disease

Management The management of syphilitic aortic insufficiency is similar in most respects to the management of congestive heart failure in general as discussed in Chap 226 Once heart failure has developed the value of antisyphilitic therapy is dubious

Coronary Ostial Stenosis as the Result of Syphilis. This condition is especially frequent when the coronary arteries take their origin *somewhat distal to* the usual site and slightly above the sinus of Valsalva In the chronic form which develops slowly the *condition may produce no symptoms if the* collateral circulation is adequate However the picture may be that of angina pectoris in a relatively *young patient with syphilis of unexplained* rapidly progressive congestive failure of syncopal attacks (rarely) or a combination of these states The acute *form occurs as the result of sudden* swelling of the aortic wall leading to partial or complete occlusion of one of the coronary ostiums as a manifestation *of the Herxheimer reaction* which occurs when a previously untreated patient with tertiary syphilis is administered a strongly spirochetocidal drug *Here the picture tends to resemble that of myocar*dial infarction and the condition can be fatal within a few days The prevention of such reactions is *discussed with the treatment of syphilitic aortitis* (Chaps 153 and 229)

THYROTOXICOSIS

Thyrotoxicosis of itself does not cause angina pectoris but when it occurs in an individual with coronary arteriosclerosis the increased oxygen needs of the heart may precipitate this disorder Thyrotoxicosis may also lead to congestive failure This complication is uncommon before the age of *forty* and usually occurs in individuals who already suffer from some other form of heart disease although occasionally congestive failure *may appear in per*sons who after cure of the hyperthyroidism present no recognizable cardiac abnormalities In some

older patients the characteristic features of thyrotoxicosis may continue to be so conspicuous even after the development of congestive failure that the diagnosis is simple However in other individuals the recognition of the underlying thyrotoxicosis as the cause of the heart failure may not be made so readily The eye phenomena and the enlargement of the thyroid gland may not be present but these difficulties are not peculiar to the problem of conjoined cardiac failure When in addition the tachycardia is reasonably attributable to the condition of the heart the increased appetite is diminished by the passive congestion of the viscera the loss of weight obscured by the gain due to edema and the warmth and flushing of the skin and the sensitivity to heat modified by the antagonistic effects of cardiac failure it is not surprising that the basic overactivity of the thyroid is hardly discernible

Despite these difficulties thyrotoxicosis should nevertheless be recognized or suspected as an underlying etiologic factor in patients with cardiac disease when any of the following phenomena occur persistent tachycardia that endures after prolonged rest attacks of paroxysmal auricular fibrillation especially in the absence of mitral disease auricular fibrillation in which the ventricular rate is resistant to the slowing effect of full doses of digitalis high output failure in the absence of any other recognizable cause

Even when thyrotoxicosis is suspected as the cause of congestive heart failure the firm establishment of the diagnosis is confronted with additional difficulties Measurement of the basal metabolic rate becomes unreliable in the presence of heart failure which in itself tends to bring about an increase in oxygen consumption because of the increased respiratory effort incident to dyspnea Hence in a patient with heart failure a moderate increase in the basal metabolic rate (up to +25 to +30 per cent) cannot be taken as proof of the existence of overactivity of the thyroid In such cases of heart failure where the role of thyrotoxicosis is in doubt determination of the level of the protein bound iodine or of the rate of uptake of radioiodine may be decisive These procedures may occasionally lead to the detection of thyrotoxic heart disease even when the basal metabolic rate is within normal limits Another important clinical method of establishing the presence of thyrotoxicosis in such cases is the favorable response to the administration of iodine or one of the antithyroid compounds

The treatment of thyrotoxic cardiac disease is essentially a combination of the management of thyrotoxicosis (Chap 64) and that of heart failure as will be discussed later

THIAMINE DEFICIENCY (Beriberi Heart Disease)

A careful history as regards dietary habits and alcoholism should be obtained from all patients with congestive heart failure Elderly males who live alone are particularly likely to have dietary deficiency states

The classic full blown picture of beriberi heart failure is characterized by cardiac dilatation passive congestion and the presence of high output failure Various nonspecific electrocardiographic changes may be present When these findings occur in an individual who gives a history of prolonged dietary insufficiency and who presents other manifestations of vitamin or other nutritional defects and in whom no other cause for the heart failure can be ascertained and when digitalis confers no benefit whereas thiamine brings about a dramatic response the heart becoming smaller and the congestive phenomena disappearing the diagnosis may be considered to be clearly established However not all cases conform completely to this pattern Probably the most important deviation lies in the response to thiamine Not all patients respond quickly spectacularly and completely to the administration of this vitamin In some the improvement takes place slowly over the course of several weeks in others an apparent cure may be followed by recurrent bouts of congestive failure indicating that in them the vitamin deficiency has culminated in irreversible changes in the myocardium that have permanently impaired its efficiency In the favorable cases enlargement of the heart and nonspecific electrocardiographic changes disappear

Clinical and experimental evidence indicates that cardiac involvement is more likely to develop when partial rather than complete thiamine deficiency has been present for a long period of time when the individual has participated in prolonged strenuous labor and when the metabolism and carbohydrate intake have been elevated thus increasing the thiamine requirement

In the United States primary thiamine deficiency is an uncommon cause of congestive failure nevertheless in an individual suffering from myocardial failure the possibility of beriberi heart disease should be considered when the diet has been grossly defective Thiamine deficiency should also be considered as a possible contributing factor in patients with any of the more common primary causes of congestive failure when there is reason to believe that anorexia has been responsible for an inadequate diet Hence all patients with congestive failure whose response to the usual measures is unsatisfactory should be given a trial with thiamine therapy this is especially important in the case of hyperthyroidism

ANEMIA

In many patients with the commoner types of heart disease anemia as the result of intercurrent disorders constitutes an important aggravating factor However severe anemia may in itself produce congestive failure especially in elderly patients

In chronic anemia when the hemoglobin falls to 7 Gm or less tissue hypoxia leads to a decline in peripheral resistance and this in turn may cause a rise in cardiac output and tachycardia At the same time coronary flow may increase as the oxygen content of the blood decreases It is the continued effect of the sustained increase in cardiac output and the inability of the coronary bed to expand beyond a certain limit in the effort to augment adequately the supply of impoverished blood to the myocardium that is responsible for the cardiac dilatation and ultimate failure in some instances of severe anemia Failure is especially likely to occur when cardiac reserve is already compromised either by the involutionary changes of age or by concomitant heart disease

The clinical picture is that of high-output failure with anemia Exact diagnosis may be difficult because severe anemia alone may cause loud systolic murmurs and less commonly diastolic murmurs thus mimicking the features of organic valvular damage This is particularly true in patients with sickle-cell anemia in whom the associated fever and joint pains may lead to confusion with acute rheumatic fever

There are other patients with severe anemia who display failure without tachycardia or the clinical signs of increased cardiac output The reasons for the absence of these compensatory mechanisms are unknown

In patients with heart failure due to anemia digitalis is relatively ineffective treatment consists essentially of the other usual means of managing congestive heart failure plus the treatment of anemia, which naturally depends on the cause Because of the risk of intensifying the congestive failure transfusions of whole blood are generally avoided When myocardial failure and anemia are severe erythrocytes free from plasma, may be administered in small daily doses In less urgent cases management of the anemia alone ill permit a gradual readjustment of the coronary bed to the increasing blood volume

Anemia may also be responsible for the appearance of angina in a person with subclinical coronary sclerosis or it may aggravate an already existent angina This is because of the inability of the sclerotic arteries to dilate adequately in response to the demands imposed by the anemia

ARTERIOVENOUS FISTULA

Arteriovenous fistula is usually the result of a penetrating injury such as a knife or bullet wound Congenital fistulas usually multiple also occur

Pathologic Physiology The initial effect of the leakage is a diminution of effective blood volume by the amount of blood that leads into and is sequestered in the involved extremity The fall in blood pressure leads to an increase in heart rate and a generalized vasoconstriction Nevertheless despite the peripheral vasoconstriction the total peripheral resistance is diminished because of the predominant effect of the leakage Renal vasoconstriction causes a fall in glomerular filtration rate and this plus increased tubular sodium reabsorption leads to an increased blood volume Cardiac output increases and this must be attributed in part or chiefly to the moderate tachycardia and to the increased stroke volume (increased systolic emptying against a lowered peripheral resistance) The heart enlarges long before myocardial failure supervenes—this must imply an increased diastolic volume and at least a slight increase in filling pressure even though right atrial pressure remains within a normal range If these assumptions are correct a third factor contributing to the increased cardiac output may be postulated Eventually the heart fails when the myocardium is incapable of coping with the burden of the sustained elevation of cardiac output

Symptoms and Diagnosis The diagnosis of arteriovenous fistula is not difficult if one keeps the possibilities in mind The swelling and increased warmth in the vicinity of the fistula the continuous murmur with systolic accentuation usually associated with a thrill the enlargement of the heart with the bounding pulse the slowing of the heart when the fistula is compressed (Branham s sign) constitute a characteristic clinical picture When myocardial failure develops the features are those of the high output type Even if an arteriovenous fistula is not immediately apparent, cardiac failure with outspoken peripheral signs of aortic insufficiency without the murmur of that lesion should lead to a careful inquiry into possible previous injuries and wounds and the search for a fistula Since extensive Paget s disease leads to heart failure on essentially the same basis—the development of innumerable AV fistulas in the abnormal bone—it should also be borne in mind under these circumstances

Pulmonary arteriovenous fistulas are rare and practically always congenital probably representing one variant of hereditary telangiectasis The clinical pattern resembles that of the cyanotic types of congenital heart disease and is characterized by cyanosis clubbing of fingers and polycythemia with negative cardiac findings Systolic or continuous

murmurs may be audible over the lungs Hemoptysis is common The diagnosis is confirmed by x ray demonstration of rounded or lobulated pulsating shadows In doubtful cases angiocardiographic studies are definitive

Successful surgical removal of the fistula nearly always leads to dramatic improvement and ultimate disappearance of the manifestations referable to the heart

PRIMARY RETENTION OF SODIUM

Retention of sodium plays an important role in all forms of congestive heart failure regardless of the cause In relatively rare instances acute sodium retention may be a primary cause of cardiac failure Whether sodium retention and the subsequent increase in plasma volume is the cause or the result of the heart failure that frequently complicates acute nephritis is not yet clear and the same is true of the heart failure resulting from the excessive administration of desoxycorticosterone acetate Under these conditions the blood pressure increases rapidly and at the same time the clinical features of increased cardiac output make their appearance

MYXEDEMA

This disorder may affect the heart in a number of different ways First the associated hypercholesteremia favors the development of coronary arteriosclerosis and angina pectoris Second myxedema may be complicated by pericardial effusion which develops slowly and rarely if ever causes tamponade The usual signs of effusion may be lacking Finally myxedema may produce electrocardiographic changes with lowered voltage of all the waves Actual myocardial failure due to myxedema occurs rarely if ever

Among the cardiac findings which should lead to a suspicion of myxedema as a possible cause of the cardiac manifestations are bradycardia despite marked enlargement of the cardiac silhouette low voltage of all waves in the electrocardiogram and dramatic decrease of the cardiac size upon the administration of desiccated thyroid gland Since coronary and cerebral arteriosclerosis are common in persons with myxedema either anginal attacks or psychic disorders may be induced by rapid elevation of metabolic rate Hence thyroid should be administered with great caution

MYOCARDITIS

Formerly many conditions of noninflammatory nature including enlargement secondary to hypertension or to valve lesions and senile myocardial degeneration were grouped together under the term *chronic myocarditis* A reaction against such terminology led to an almost complete abandonment of the term *myocarditis* as a diagnosis but in recent years with a better recognition of its limitations the term is again and more properly being used

Acute myocarditis with pronounced clinical manifestations may be due to rheumatic fever diphtheria collagen disease or scrub typhus Almost any acute infectious process may cause inflammatory changes in the myocardium but clinically significant findings are rare The diagnosis is justified when evidence of heart disease and more especially gallop rhythm increase in size conduction defects and other electrocardiographic changes set in during or following acute infection Except for the types complicating rheumatic fever and diphtheria the prognosis is good and in the rare instance of fatal circulatory collapse it is difficult to estimate the respective roles of the myocarditis and of the virulence of the infection Diphtheritic myocarditis commonly is fatal when it is sufficiently severe to produce clinical manifestations In the milder instances with slight electrocardiographic and no clinical manifestations complete recovery occurs Although immediate recovery from rheumatic myocarditis usually takes place long term impairment of the heart is the rule The management is that of the underlying disease process plus that of congestive failure when this complication supervenes Digitalis rarely has a dramatically beneficial effect on any type of acute myocarditis

Chronic myocarditis may be of known or unknown cause The known causes include such rare disorders as tuberculous myocarditis and trichinosis of the myocardium When a more or less diffuse inflammatory lesion of unknown etiology is confined to the myocardium all other evidences of a related infection or other disorder being absent the condition is designated as *isolated* or *Fiedler's* myocarditis rarely recognized during life

TRAUMATIC HEART DISEASE

Cardiac damage may be due to both penetrating and nonpenetrating injuries to the heart the most frequent cause of the latter being the automobile accident though any heavy blow to the chest wall may be responsible Serious injury of the heart may ensue though there is no external sign of bruise Any structure of the heart may be affected (see Fig 161 Chap 223)

The valve cusps may be torn usually the mitral or aortic and the appearance of a loud murmur in a previously healthy person is followed by rapidly progressive myocardial failure A coronary artery may be injured and myocardial infarction may ensue or the same clinical picture may follow severe myocardial contusion in both instances character

istic alterations in the ventricular complexes of the electrocardiogram are displayed Various disturbances of the heart rhythm may be seen the authors have encountered at least two cases of bundle block presumably incurred as a result of boxing, and complete AV block has been reported Hemorrhage into the pericardium with tamponade may follow a tear of the myocardium or of the pericardial vessels or of a coronary branch Obliteration of the pericardial sac may follow pericardial hemorrhage and the electrocardiogram may reveal permanently inverted T waves

Treatment for myocardial failure due to rupture of the valves is hardly ever effective If the symptoms are those of infarction it is impossible to distinguish between contusion and coronary artery injury in any case the treatment is the same and is that accorded the patient with infarction Pericardial tamponade has been managed successfully by repeated taps alone Other investigators advocate immediate surgical intervention or intervention if tamponade recurs after two taps

MALIGNANT CARCINOID (Argentaffinoma)

The clinical picture associated with malignant carcinoid is characterized by episodic flushing cyanosis telangiectasia of face and the frequent though not constant involvement of the right heart when liver metastases are present Pulmonic stenosis with tricuspid insufficiency leads to right ventricular hypertrophy and finally failure with systemic venous engorgement It is believed that these various cardiovascular manifestations are due to the excessive quantities of serotonin (5-hydroxytryptamine) released into the circulation by the primary tumor and liver metastases It has been believed but not proved that the right heart lesions are part of a widespread connective tissue disorder the left heart being spared because serotonin is destroyed in its passage through the lung

The combination of pulmonic stenosis and cyanosis brings up the possibility of confusion with congenital pulmonic stenosis with a patent foramen ovale In the latter case the cyanosis with polycythemia is due to a right left shunt causing arterial hypoxemia In the former abnormal arterial oxygen unsaturation is absent the cyanosis without polycythemia being due to alterations in the cutaneous vasculature

HEART DISEASE OF OBSCURE ETIOLOGY

Obscure etiology is meant here to imply that a form of heart disease is encountered that does not appear to belong to any of the more common categories previously described In some of these cases continued observation may reveal a hitherto unrecognized structural lesion such as aortic stenosis or a mitral valve defect An unexpectedly poor response to therapy or the manifestations of high output failure may lead to the discovery of marked thyrotoxicosis In still others autopsy examination may disclose previously undetected lesions such as a relatively common type of congenital heart disease or the scars of healed infarcts or a valvular lesion In other words many cases of obscure etiology are simply unrecognized examples of common heart disease Nevertheless even if one gives thoughtful consideration to this reminder one is forced at times by one or another puzzling clinical feature of heart disease to speculate on the possibility that an unusual type of heart disease may actually be present Frequently the problem revolves about the patient without apparently significant murmurs or pulmonary disease or hypertension or clear cut coronary disease (anginal pain myocardial infarction)

When this situation arises in an elderly person it is hardly ever considered a problem since this type of case almost by definition is labeled arteriosclerotic heart disease However it has been pointed out previously that the absence of an obvious etiologic factor does not *ipso facto* justify the diagnosis of arteriosclerotic cardiac disease in an elderly patient without anginal pain because the same problem arises in young adults and even in children The following are some of the more unusual forms of heart disease to be considered

Endocardial Fibroelastosis This disorder occurs most frequently in infants but adults of all ages may be afflicted At autopsy the findings are identical in both marked cardiac hypertrophy more or less generalized thickening of the endocardium chiefly of the left ventricle and frequently mural thrombi The clinical picture is that of gradual or rapidly progressive heart failure occasionally typical angina pectoris systolic murmurs that seem inadequate to account for the considerable enlargement of the heart frequent episodes of systemic embolization irregularities of rhythm and nonspecific electrocardiographic abnormalities In the older person particularly when angina is present differentiation of this disease from coronary sclerosis is difficult if not impossible In younger patients under forty the disorder may be suspected when the clinical picture fails to conform with one of the common causes of heart disease at that age and when repeated arterial embolization occurs The cause is unknown but in infants at least the best explanation appears to be intrauterine hypoxia due to premature closure of the foramen primum or foramen ovale

An identical clinical picture with *endocardial fibrosis and subendocardial necrosis* has been described as occurring frequently in certain African

tribes. In some of these patients there is evidence that nutritional deficiencies are at least partially responsible; in others there is no clear cut relationship to nutritional disorder. What connection their illness has with a practically identical one occurring in this country, usually designated as *idiopathic hypertrophy of the heart*, is not clear. In idiopathic hypertrophy of the heart many patients give a history of long standing alcoholism and inadequate diet, but no specific nutritional defect has been proved. The term *cardiovascular collagenosis* has been applied to this group because of the histologic demonstration of degeneration of collagen fibers and of the associated ground and cement substances.

The recognition of cardiac involvement by *sarcoidosis, scleroderma, hemachromatosis or amyloid disease* will depend on the demonstration of these disorders elsewhere in the body by biopsy or other precise methods. The same would be true of the other well defined *collagen diseases*. Pericarditis is so common in disseminated lupus and occasionally in periarteritis nodosa that these diseases must be considered when pericarditis of uncertain origin is encountered. Scleroderma and amyloid disease may present a picture identical with that of constrictive pericarditis.

Neoplasms of the Heart. With the exception of myxoma of the left atrium, primary tumors of the heart (rhabdomyoma, mesothelioma of the pericardium, a variety of other benign tumors or their malignant counterparts) are medical curiosities. *Myxoma of the atrium*, usually of the left, is also rare but presents a more distinctive clinical picture and the possibility of surgical cure. This condition should not really be considered in a discussion of heart disease of obscure origin because almost invariably myxoma is diagnosed as mitral stenosis and recognized at operation. Myxomas of the atrium may display the characteristic features of ball valve thrombus: variability of the murmurs of mitral stenosis with change of position, syncope, paroxysms of acute pulmonary edema—all due to sudden and intermittent obstruction of the mitral orifice.

Table 113 CHIEF CLINICAL FEATURES OF SOME OF THE RARER CARDIAC DISORDERS *

Etiologic group	Specific disorder	Important clinical features: Cardiac	Important clinical features: Noncardiac	Accessory features	Remarks
Infectious	Scrub typhus	Enlargement Gallop	Eschar, fever	ECG nonspecific changes	Orient and tropics
	Diphtheria	Arrhythmias Failure	Nasopharyngitis Ulcers of skin	Kleb-Loeffler bacillus	Grave prognosis
	Chagas disease	Enlargement	Anemia Debility	Antibodies to *Trypanosoma cruzi*	Sudden death frequent
	Trichinosis	Enlargement	Muscle pains	Eosinophilia	Ingestion of raw pork
Metabolic	Xanthomatosis	Angina pectoris	Xanthomas Xanthelasma	Hypercholesteremia	Family history
	Von Gierke's disease	Enlargement	Enlarged liver	Hypoglycemia	Infants
	Cardiac amyloidosis	Enlargement Failure	Often none	Congo red test of no value	Other features of amyloidosis may be absent
Therapeutic	Excessive intravenous fluids	Dilatation Failure	Evidence of the primary disease	Hemodilution	Especially elderly persons
	Emetine	Tachycardia Hypotension	Evidence of the primary disease	T wave inversion	
	Desoxycorticosterone	Enlargement	Hypertension Edema	Hemodilution	
Miscellaneous	Acute nephritis	Enlargement Gallop	Hypertension Edema	Hematuria Proteinuria	
	Polyarteritis	Enlargement Pericarditis	Fever Arthritis	Leukocytosis Eosinophilia	Bizarre clinical picture
	Libman-Sacks disease	Enlargement Pericarditis	Fever, arthritis, lupus of face	Leukopenia	Young females, atypical verrucous endocarditis
	Post partum heart failure	Enlargement Failure	Recent delivery		
	Myocardial sarcoidosis	Enlargement Failure	Enlarged spleen, liver, nodes	Hilar shadows Bone lesions Increased globulin	Slight fever, cutaneous lesions

* The list is not comprehensive, as many disorders are omitted. None of the types due to curable causes are listed since they have been considered in the text.

Secondary tumors of the heart are much more frequent and have been described as occurring in 10 to 20 per cent of cases of malignancy The most common form is by direct extension to the pericardium of a primary carcinoma of the breast or bronchus malignant thymoma or lymphoma The clinical picture is usually that of rapidly recurring pericardial effusion often bloody Metastases to the myocardium are rarely responsible for symptoms or signs that permit recognition although suspicion should be aroused when the development of intractable failure or of a distinctly abnormal electrocardiogram takes place in a person known to harbor other metastatic lesions and previously free of heart disease

There is a logic in the diagnosis of a rare cardiac disorder such as pericardial disease in the presence of known malignant disease of the mediastinum or sarcoid heart disease when sarcoidosis has been demonstrated elsewhere in the body One should bear in mind however that the diagnosis of many of these conditions can hardly be anything other than a lucky guess often the artificial by product of the "C P C" atmosphere and that a lengthy and detailed differentiation can only be a tale full of sound and fury signifying nothing

Geographic factors are sometimes of importance in determining the cause of heart failure of obscure origin Residence in areas where *Schistosomiasis mansoni* is endemic should bring to mind the possibility that this disease may cause cor pulmonale while cardiac trypanosomiasis (Chagas disease) should be considered in persons living in northern and central South America In the Orient heart failure is sometimes due to scrub typhus

Since cure or significant amelioration of certain forms of heart disease is now possible they must always be borne in mind when an obscure form of heart disease is encountered Thus one should search carefully for bacterial endocarditis the various causes of high output failure certain types of congenital heart disease constrictive pericarditis and cor pulmonale due to thromboembolic disease

Some of the pertinent features of a few of the many rarer cardiac disorders are summarized in Table 113

PERICARDITIS

Pericarditis may be classified according to two different methods both of practical importance

I Etiologic and prognostic classification
  A Infectious
    1 Mild (benign pericarditis)
    2 Grave (including rheumatic tuberculous and pyogenic)
  B Noninfectious
    1 Uremic (prognosis usually grave)
    2 Ischemic (myocardial infarction)
    3 Neoplastic (rare)
  C Uncertain etiology
    1 Polyarteritis
    2 Disseminated lupus erythematosus
II Morphologic and clinical classification
  A Acute
    1 Fibrinous (without significant effusion)
    2 Serofibrinous (with significant effusion)
  B Chronic
    1 Constrictive (usually due to tuberculous or pyogenic infection or to collagen disease)
    2 Adhesive mediastinopericarditis (usually rheumatic)

General Comments Pain is usually indicative of an infectious type of pericarditis but this is a rule to which there are frequent exceptions Pain may be absent in a slowly developing tuberculous pericarditis and it may occur occasionally in the pericarditis of disseminated lupus or renal failure although in the latter it is rarely a prominent symptom probably because of the stuporous or comatose state of the patient Postinfarctional pericarditis is practically always painless nevertheless the characteristic pleuritic type of pain of the infectious type may be encountered rarely when there is no other evidence of infection Moreover the sudden development of hemopericardium especially following the administration of anticoagulants may be associated with severe pain

Pericarditis causes three distinct types of pain By far the most common is the pleuritic variety related to respiratory movements and always aggravated by deep inspiration or cough This type of pain is due to the pleuritic component of the pleuropericarditis so commonly present in the infectious forms It may be felt in the region of the left border of the heart or the upper abdomen or back (intercostal nerve involvement) or it may be experienced at the left shoulder and trapezius ridge (phrenic nerve involvement) The next most common pericardial pain is the steady crushing substernal pain identical with that of acute myocardial infarction if the pleuritic pain is absent differentiation on the basis of the pain alone is impossible The third type of pericardial pain one that a priori should appear to be the most common and characteristic is actually quite uncommon this pain is synchronous with the heart beat and is felt at the left border of the heart and left shoulder Rarely all three types may be present simultaneously

The *pericardial friction rub* is the most important physical sign sometimes elicited only when firm pressure with the stethoscope is applied to the chest

tribes. In some of these patients there is evidence that nutritional deficiencies are at least partially responsible; in others there is no clear-cut relationship to nutritional disorder. What connection their illness has with a practically identical one occurring in this country, usually designated as *idiopathic hypertrophy of the heart*, is not clear. In idiopathic hypertrophy of the heart many patients give a history of long-standing alcoholism and inadequate diet, but no specific nutritional defect has been proved. The term *cardiovascular collagenosis* has been applied to this group because of the histologic demonstration of degeneration of collagen fibers and of the associated ground and cement substances.

The recognition of cardiac involvement by *sarcoidosis, scleroderma, hemachromatosis, or amyloid disease* will depend on the demonstration of these disorders elsewhere in the body by biopsy or other precise methods. The same would be true of the other well-defined *collagen diseases*. Pericarditis is so common in disseminated lupus and occasionally in periarteritis nodosa that these diseases must be considered when pericarditis of uncertain origin is encountered. Scleroderma and amyloid disease may present a picture identical with that of constrictive pericarditis.

Neoplasms of the Heart. With the exception of myxoma of the left atrium, primary tumors of the heart (rhabdomyoma, mesothelioma of the pericardium, a variety of other benign tumors or their malignant counterparts) are medical curiosities. *Myxoma of the atrium*, usually of the left, is also rare but presents a more distinctive clinical picture and the possibility of surgical cure. This condition should not really be considered in a discussion of heart disease of obscure origin, because almost invariably myxoma is diagnosed as mitral stenosis and recognized at operation. Myxomas of the atrium may display the characteristic features of ball-valve thrombus: variability of the murmurs of mitral stenosis with change of position, syncope, paroxysms of acute pulmonary edema—all due to sudden and intermittent obstruction of the mitral orifice.

Table 113 CHIEF CLINICAL FEATURES OF SOME OF THE RARER CARDIAC DISORDERS *

Etiologic group	Specific disorder	Important clinical features		Accessory features	Remarks
		Cardiac	Noncardiac		
Infectious	Scrub typhus	Enlargement Gallop	Eschar, fever	ECG nonspecific changes	Orient and tropics
	Diphtheria	Arrhythmias Failure	Nasopharyngitis Ulcers of skin	Klebs-Loeffler bacillus	Grave prognosis
	Chagas' disease	Enlargement	Anemia Debility	Antibodies to *Trypanosoma cruzi*	Sudden death frequent
	Trichinosis	Enlargement	Muscle pains	Eosinophilia	Ingestion of raw pork
Metabolic	Xanthomatosis	Angina pectoris	Xanthomas Xanthelasma	Hypercholesteremia	Family history
	Von Gierke's disease	Enlargement	Enlarged liver	Hypoglycemia	Infants
	Cardiac amyloidosis	Enlargement Failure	Often none	Congo red test of no value	Other features of amyloidosis may be absent Especially elderly persons
Therapeutic	Excessive intravenous fluids	Dilatation Failure	Evidence of the primary disease	Hemodilution	
	Emetine	Tachycardia Hypotension	Evidence of the primary disease	T wave inversion	
	Desoxycorticosterone	Enlargement	Hypertension Edema	Hemodilution

	Polyarteritis	Enlargement Pericarditis	Fever Arthritis	Leukocytosis Eosinophilia	Bizarre clinical picture
	Libman-Sacks disease	Enlargement Pericarditis	Fever, arthritis, lupus of face	Leukopenia	Young females, atypical verrucous endocarditis
	Post partum heart failure	Enlargement Failure	Recent delivery		
	Myocardial sarcoidosis	Enlargement Failure	Enlarged spleen, liver, nodes	Hilar shadows Bone lesions Increased globulin	Slight fever, cutaneous lesions

* The list is not comprehensive, as many disorders are omitted. None of the types due to curable causes are listed, since they have been considered in the text.

proach to the pericardium the authors prefer the one just lateral to the apex When pericardial effusion recurs rapidly and frequently a pleuropericardial window may be established If pericardial effusion is of obscure origin and long duration exploration is justifiable for the purpose of establishing etiology and of instituting specific therapy

Acute Benign Infectious Pericarditis

This disorder is an important clinical entity because of its frequency and because it may be confused with other more serious affections It is presumed to be due to a viral infection but this is unproved It occurs at all ages but most commonly in young adults Often there is a history of an antecedent respiratory infection within the preceding 2 or 3 weeks Fever and pericardial pain appear at about the same time an important feature in the differentiation from myocardial infarction Fever and other constitutional symptoms are usually mild to moderate but occasionally the initial symptoms are stormy with fever rising to 104 to 105 F The disease ordinarily runs its course in a few days to 2 weeks Tamponade is exceptional and subsequent constrictive pericarditis is very rare As is true in other forms of acute pericarditis the pain is usually aggravated by breathing change of position or swallowing The T wave alterations in the electrocardiogram may persist for several years or indefinitely constituting a subsequent source of confusion in persons without a clear history of pericarditis It is possible that some such infection may be the explanation of the soldiers patch a localized thickening of the visceral pericardium sometimes observed at autopsy Since there is no specific test for the disorder the diagnosis is primarily one of exclusion The important points to keep in mind are to avoid the error of considering the illness to be due to myocardial infarction when the predominant symptom is a steady unwavering substernal pain and also to avoid disregarding the possibility of other more serious causes such as disseminated lupus or tuberculosis simply because the initial course is mild In most cases neither the tetracyclines nor any other specific form of therapy has any value

Other Types of Infectious Pericarditis

The more serious and common forms include those due to rheumatic fever tuberculosis and pyogenic infections The *rheumatic type* is practically always associated with other evidences of severe carditis and usually preceded or followed by valvular damage Pericardial effusion sometimes responds favorably to salicylates even though the carditis is otherwise uninfluenced

Tuberculous pericarditis occurs most commonly over the age of forty and usually in an individual with obvious pulmonary pleural or peritoneal tuberculosis but also when evidence of tuberculosis elsewhere is absent The infection probably reaches the pericardium by direct extension from the mediastinal lymph nodes and it commonly terminates in constrictive pericarditis The clinical picture may vary from one that resembles acute benign infectious pericarditis to one without a history of pain the symptoms being those of infection in an individual with massive effusion with or without manifestations of tuberculous involvement of other structures It is important to bear this condition in mind when a middle aged or elderly person with fever presents signs of pericarditis The prognosis was formerly very grave 90 per cent dying within a few months one important factor being the frequency of miliary tuberculosis With the newer antimicrobial drugs the mortality has been very much reduced The initial management of tuberculous pericarditis is that of tuberculosis in general with vigorous use of the newer drugs (p 933) In addition the usual measures to combat cardiac ascites and edema (p 1313) may be necessary Constrictive pericarditis develops in most instances and calls for surgical therapy after the active process has been controlled

Purulent pericarditis is now far less common than before the advent of effective antibiotics particularly for the treatment of pneumonia Once pyogenic pericarditis has been recognized surgical intervention should be undertaken unless antibiotic therapy is rapidly effective

Noninfectious Pericarditis

The two most common causes of noninfectious pericarditis are uremia and myocardial infarction In both instances the involvement of the pericardium is a relatively unimportant feature except in the occasional case of postinfarctional hemorrhagic pericarditis due to anticoagulant therapy This latter should be kept in mind when the patient with an acute infarction develops recurrent chest pain and evidence of pericardial effusion in which case cessation of anticoagulants administration of vitamin K_1 oxide (Mephyton) and possibly pericardial tap may be of crucial importance

Neoplastic pericarditis occasionally occurs as the result of invasion of the pericardium by malignant tumors of adjacent structures The condition is rare and has little practical importance

Pericarditis Due to Collagen Disease The most important is that due to disseminated lupus in which disease it occurs at some time in its course in over 50 per cent of the cases Often it appears as an asymptomatic effusion at other times pain is present and very rarely tamponade may develop When it occurs in the absence of other evidences of the underlying disorder differentiation from

wall The pericardial rub is likely to be inconstant and transitory and a loud to and fro leathery sound may disappear within a few hours possibly to re appear the following day The electrocardiogram usually displays elevation of the S T segments in several leads without reciprocal depressions in others or significant changes in the QRS complex Later the T waves become inverted and in some instances this latter change is permanent

When an effusion develops the fluid nearly always has the physical characteristics of an exudate Bloody fluid is most commonly due to tuberculosis or tumor but it may also be found in the pericarditis of rheumatic fever uremia the acute benign infectious form and of course in the hemopericardium following infarction

Tamponade When fluid in the pericardium accumulates in an amount sufficient to cause serious obstruction to the inflow of blood to the ventricles *tamponade* is said to be present The amount of fluid necessary to produce this critical state may be as small as 250 to 300 ml when the fluid develops rapidly or it may be over 1 000 ml in slowly developing effusions when the pericardium has had the opportunity to stretch and adapt to the increasing fluid Tamponade is usually due to tuberculosis pyogenic infection or tumor but it may occur in rheumatic fever acute benign pericarditis disseminated lupus erythematosus or postinfarctional hemopericardium The symptoms are primarily due to the sudden fall in cardiac output and systemic congestive failure Orthopnea with little or no pulmonary congestion is also prominent the mechanism of this dyspnea is not understood The physical signs are the increase in the contour of the heart especially important when this has occurred under observation increasing heart rate and falling blood pressure with narrowed pulse pressure distention of the neck veins and rapid enlargement of the liver The heart sounds tend to become faint but they may remain loud the friction rub may disappear or remain clearly audible the apex beat may disappear but sometimes is felt well within the left border The distention of the neck veins is increased during inspiration or when pressure is applied with the palm of the hand over the liver (hepatojugular reflex) This phenomenon is due to the inability of the right ventricle to accommodate the increased inflow of blood and the consequent reflux of blood into veins already under increased tension A protodiastolic gallop is often heard Very important is the appearance of a distinctly percussible right border of the heart extending more than 5 cm from the midline On fluoroscopic examination the ventricular pulsations are usually diminished or absent

One of the most important clues is the *paradoxic pulse* best demonstrated by taking the blood pressure in expiration and inspiration a difference of 10 mm Hg or more being considered a positive test The mechanism of the paradoxic pulse is still uncertain It occurs not only in pericardial effusion with tamponade and constrictive pericarditis but also in various conditions associated with bronchial obstruction and in severe congestive failure with peripheral vascular collapse The probable explanation for the phenomenon is that it represents an exaggeration of the normal disproportion between right ventricular output and the capacity of the pulmonary vascular bed during inspiration Normally during inspiration the fall in intrathoracic pressure causes increased filling of the right ventricle because of the increased gradient of pressure between the extrathoracic veins and the right chambers of the heart The left ventricle which draws blood from intrathoracic structures is relatively unaffected Right ventricular output increases but at the same time the pulmonary vascular bed is increased disproportionately the net result being a diminished flow to the left side of the heart and a corresponding reduction in left ventricular output In cardiac tamponade flow into the right ventricle is impeded and right ventricular output is small and fixed However the inspiratory enlargement of the pulmonary vascular bed is relatively uninfluenced and the normal slight reduction of flow into the left side of the heart is exaggerated It is the corresponding drop in left ventricular output that is responsible for the inspiratory fall in blood pressure

X ray findings are often inconclusive and there is no one configuration that is constant and pathognomonic *A large cardiac shadow with complete absence of visible pulsations associated with absence of pulmonary congestion is more convincing evidence of pericardial effusion* In some instances angiocardiography has provided decisive proof of the existence of pericardial effusion

One should not be misled into an incorrect diagnosis of pneumonia by signs of consolidation of the left lower lobe as these are not infrequent in the presence of massive pericardial effusion (Ewart s sign) It is also important to bear in mind that differentiation between cardiac tamponade and severe myocardial failure may sometimes be exceedingly difficult The decision is a matter of great practical importance because digitalis has no beneficial effect in instances of cardiac tamponade while lessening of the intrapericardial pressure by pericardial tap may be lifesaving

Treatment Patients with pericarditis should be observed with care and if signs of effusion develop the blood pressure and heart rate should be recorded at hourly intervals If the symptoms and signs of tamponade appear pericardial paracentesis should be instituted at once since relief of pressure may be lifesaving Of the various methods of ap

pericardial paracentesis Thus the diagnosis of con strictive epicarditis is made when the removal of a large amount of fluid from the pericardial sac fails to cause a sharp decline in the previously elevated venous pressure Operative treatment is especially effective in patients with this condition

Chronic Adhesive Mediastinopericarditis This condition is an exceedingly rare result of rheumatic infection the heart being bound to the surrounding structures by dense adhesions The condition is almost invariably associated with rheumatic lesions of the mitral valve Diagnosis depends mainly on the demonstration of Broadbent s sign systolic re traction of the posterior left lower interspaces but since the same phenomenon may be witnessed whenever the heart is greatly enlarged it must be concluded that diagnosis of the condition is at best uncertain and probably impossible Favorable re sults have been reported in a few instances follow ing removal of the ribs in the precordial and left axillary regions in order to allow the heart to pull against soft tissue rather than bone

acute benign infectious pericarditis or a mild form of tuberculous pericarditis may be made only on discovery of L E cells Pericarditis due to periarteritis is rarely of significance

Chronic Pericarditis

Constrictive Pericarditis This disorder results when the healing of acute fibrinous or serofibrinous pericarditis results in obliteration of the cavity of the sac with the formation of granulation tissue which gradually contracts forming a firm scar encasing the heart and interfering with filling The condition is usually the result of tuberculous staphylococcal or pneumococcal infection but less commonly other organisms or collagen disease may produce it The clinical picture is characterized by dyspnea on exertion which however is often relatively slight at rest while orthopnea may be entirely absent pronounced enlargement of the liver distention of the cervical veins ascites and peripheral edema The heart is normal in size in about half the cases in the others it is slightly to markedly enlarged A paradoxic pulse is frequently encountered and a protodiastolic gallop is present in most patients Both by palpation and by x ray marked diminution in cardiac pulsation is noted A very important finding is the presence of calcification of the pericardium visible by x ray in about one half the cases The spleen is sometimes palpable and in the absence of evidence of bacterial endocarditis splenomegaly in a patient with congestive heart failure should arouse suspicion of constrictive pericarditis The electrocardiogram frequently displays low voltage and flattening or inversion of the T waves in all three limb leads Auricular fibrillation is often present in this condition

Congestive failure is initially the result of tamponade with impairment of filling of both ventricles However the fibrotic process may extend into the myocardium and congestive failure may be due to the combined effects of the myocardial and the pericardial lesions The interference with filling reduces the work of the heart and myocardial atrophy may occur This probably accounts for the delayed beneficial effects of operative treatment Improvement may not become apparent until a number of months have elapsed Presumably the atrophy disappears when the impairment of filling is removed by resection of the pericardium Because the filling of the right ventricle is impaired acute pulmonary edema does not occur and orthopnea is minimal Despite the hindrance to left ventricular filling the right ventricle is unable to flood the lungs with blood

Inasmuch as the usual physical signs of cardiac disease (murmurs cardiac enlargement) may be inconspicuous or entirely lacking the presence of hepatic enlargement and intractable ascites may lead to a mistaken diagnosis of cirrhosis of the liver This error should be avoided if the veins of the neck are inspected carefully in all patients with ascites and hepatomegaly *Given a clinical picture resembling cirrhosis but with the added feature of distended cervical veins careful search for calcification of the pericardium by x ray examination and detection of the electrocardiographic signs described above may disclose a curable or remediable form of heart disease that might otherwise be overlooked*

Occasionally constrictive pericarditis will be confused with rare disorders of the endocardium or myocardium which likewise produce disproportionate impairment of filling Thus in a patient presenting the classic features of constrictive pericarditis one should consider the possibilities of constrictive endocarditis (fibroelastosis subendocardial fibrosis) and constrictive myocarditis (scleroderma amyloid disease of the heart healed eosinophilic myocarditis) before advising pericardectomy In the absence of demonstrable calcification of the pericardium or of electrocardiographic changes which are typical of pericarditis it may be impossible to differentiate these conditions from constrictive pericarditis

In the treatment of constrictive pericarditis digitalis is rarely of much value but diuretic drugs and sodium restriction are useful The benefits derived from the delicate operation of cardiac decortication are often striking and frequently the improvement while slight at first is progressive over a period of many months The patient may be restored from a state of invalidism to something approaching normal activity The operation should be performed as soon as the causative infection has become relatively inactive as indicated by the temperature and sedimentation rate in order that the scar tissue will not have become too dense Rarely fluoroscopic examination may reveal calcification of the pericardium in an individual who is free of all symptoms referable to the heart and so long as venous pressure remains normal treatment is unnecessary

Most instances of constrictive pericarditis are of tuberculous origin Streptomycin treatment during the phase of effusion may prevent the development of constriction Preoperative and postoperative administration of streptomycin may prevent spread of tuberculosis Such spread and congestive failure are the usual causes of death

Constrictive Epicarditis (*Porter s Syndrome*) Ordinarily constrictive pericarditis occurs only after fluid has been resorbed from the pericardium and results from fusion and marked thickening of the visceral and parietal layers Rarely the fluid persists and the epicardium becomes rigid but only slightly thickened resembling an egg shell In such instances the signs of tamponade persist despite

of pulmonic/systemic flow may reach 20 or more In the latter situation however the difference in oxygen saturation between arterial and venous blood is so small that accurate calculation of pulmonary flow by the usual methods of cardiac catheterization is impossible

With left to-right shunts at the atrial or ventricular level, the right ventricle is required to pump an increased volume of blood per minute at pressures which may or may not be higher than normal This results in right ventricular dilatation and hypertrophy the degree of hypertrophy being roughly proportional to the degree and duration of pulmonary hypertension When the shunt is at the level of the pulmonary artery as in patent ductus arteriosus uncomplicated by pulmonary hypertension only the left ventricle hypertrophies when pulmonary hypertension appears right ventricular hypertrophy is superimposed

Left ventricular work is increased if the site of the shunt is in the ventricular septum or distal to the left ventricle Left ventricular hypertrophy and dilatation result but may be overshadowed by simultaneous right ventricular hypertrophy

Arterial unsaturation does not occur with pure left to-right shunts but clinical cyanosis may occasionally be present as a result of decreased systemic flow or inadequate oxygenation in the lung The latter is rare

Auscultatory findings with left to-right shunts depend on the specific malformations When the shunt is distal to the mitral valve an apical mid or late diastolic murmur is often present presumably because the greatly increased blood flow across a normal mitral orifice is equivalent to relative mitral stenosis A similar diastolic murmur is sometimes present in cases of atrial septal defect although its origin is not clear

Right to-left Shunts In this condition systemic venous blood returning to the heart enters the left heart chambers or systemic arterial circuit without passing through the pulmonary capillary bed

The major signs and symptoms accompanying right to-left shunts result not only from the diversion of blood through abnormal pathways but also from the obstruction to blood flow through normal pathways (e g pulmonic stenosis) which is often present The functional effect of these abnormalities is to reduce the partial pressure of oxygen in arterial blood and to burden one or both ventricles with extra work Some of the resulting signs and symptoms are common to many different malformations and will be discussed individually

Cyanosis Cyanosis or the appearance of clinically recognizable blueness in the systemic capillaries is usually a direct result of lowered arterial oxygen saturation Slowed peripheral blood flow and inadequate saturation in the lungs can also cause cyanosis but these factors are of secondary importance in cyanotic congenital heart disease The oxygen saturation of the blood leaving the lungs is usually normal but the admixture of venous blood distal to the site of the right to-left shunt reduces the arterial saturation The degree of arterial unsaturation varies directly with the volume of the venous-arterial shunt and indirectly with the volume of pulmonary blood flow

Cyanosis is best observed in the nail beds buccal mucous membranes and lips It becomes evident clinically only when the equivalent of approximately 5 Gm per cent of unsaturated hemoglobin is present in arterial blood hence patients with anemia may not show clinical cyanosis even though the oxygen saturation of arterial blood is well below normal while polycythemia accentuates cyanosis with even minimal degrees of arterial unsaturation

In congenital heart disease cyanosis usually implies the existence of an abnormal communication between the venous and arterial sides of the circulation which may be a patent foramen ovale defect of the interatrial or interventricular septum transposed great vessels patent ductus arteriosus or other communication between the aorta and pulmonary artery or (rarely) direct entry of systemic veins into the left atrium In addition to the abnormal communication hemodynamic conditions must be such that blood flows through the opening from right to left " producing a venous arterial shunt this usually requires elevation of right atrial, right ventricular or pulmonary artery pressure above normal levels An extreme example of a structural anomaly which produces a right to-left shunt is seen in complete transposition of the great vessels in which the right ventricular outflow enters the aorta instead of the pulmonary artery In occasional cases clinical cyanosis may be due to diminished peripheral flow or other factors as in the normal vigorously crying child It is almost never due to inadequate pulmonary oxygenation

Polycythemia Polycythemia with red cell counts of 6 to 9 million per cubic millimeter and hematocrits as high as 80 develops in response to the lowered arterial oxygen tension The oxygen-carrying capacity of the blood is thereby increased partially compensating for the decreased oxygen saturation When the arterial saturation at rest is 70 per cent or more circulating hemoglobin increases to such an extent that the oxygen content of arterial blood is actually higher than normal

The polycythemia is absolute rather than relative i e the total red cell mass is increased The plasma volume is usually decreased but the red cell volume increase is of such magnitude that total blood volume is greater than normal

This adaptative response is not entirely benefi

225 CONGENITAL HEART DISEASE

William R Milnor and Henry T Bahnson

The demonstration that many congenital malformations of the heart can be treated successfully by surgery has radically changed the physician's approach to congenital heart disease Not long ago the nonspecific clinical diagnosis of *congenital heart disease* or *morbus caeruleus* was regarded as all that was possible or necessary in many cases Today the accurate recognition of specific lesions and a quantitative estimate of the burden they impose on the heart in each case is of great practical importance

The *incidence* of congenital heart disease in the general population is probably in the neighborhood of 0 3 per cent of all live births and congenital malformations constitute from 1 to 5 per cent of all cases of recognized heart disease after infancy

Etiology Many abnormalities of the heart and great vessels can be explained by failure to progress beyond an early stage of embryologic development while others seem to represent aberrant development of a normal structure The cause of these embryologic misadventures is unknown in most cases but various theories involving fetal hypoxia fetal endocarditis immunologic abnormalities vitamin deficiencies and specific genetic abnormalities have been proposed

In some cases a clear relation between maternal rubella during gestation and congenital malformations of the heart has been demonstrated It appears that maternal rubella during the first 2 months of pregnancy will lead to congenital malformations of the heart cataracts deaf mutism or other anomalies in almost all cases The later in gestation the rubella occurs the lower the incidence of congenital abnormalities but cases of congenital heart disease have occurred following rubella in the sixth month of pregnancy

In clinical practice however relatively few cases of congenital heart disease—probably less than 2 per cent—can be attributed to this cause and in most instances no significant environmental factor during fetal development can be elicited by history

Inheritance With few exceptions patients with congenital heart disease have a negative familial history for congenital malformations There are nevertheless well documented exceptions including families in which the same malformation has recurred in two or three successive generations Patent ductus arteriosus is the commonest lesion thus reported but this may simply reflect the relatively benign course of this anomaly

There is good evidence that factors concerned with some congenital abnormalities can be transmitted as mendelian recessive traits while some may arise as a result of *de novo* mutation

In practice the birth of one child with a congenital malformation of the heart does not in itself contraindicate future pregnancies since the risk that subsequent siblings will have congenital malformations is extremely small

The incidence of some congenital malformations of the heart shows clear sex differences which may be attributed to either sex linked inheritance or environmental factors in utero Defects of the atrial septum and persistent patency of the ductus arteriosus are much more common in females than in males pulmonic stenosis and ventricular septal defect show little or no sex difference coarctation of the aorta and congenital aortic stenosis affect males predominantly

PHYSIOLOGIC EFFECTS

Shunts

A cardiovascular shunt may be broadly defined as blood flow through a pathway which diverts a portion of the ventricular output from the pulmonary or systemic capillary beds It requires an open communication (or one potentially open such as a patent foramen ovale) between the pulmonary and systemic circulation the direction of blood flow being determined by the pressures existing on either side of the communicating pathway Such communications usually represent persistence of an embryonic stage of development into postnatal life Since pressures in the left heart and systemic circulation normally exceed those in the corresponding part of the pulmonary circuit shunts are usually from left to right unless the right sided pressures are pathologically increased In some cases changing pressure gradients through the heart cycle will produce shunts which vary in direction In other instances the existence of roughly equivalent pressures on opposite sides of a defect may prevent shunting of blood even though the defect may be large Streamlining of flow appears to be an important factor in some instances and may produce shunting in the absence of measurable pressure gradients

Left to-right Shunts In this situation a portion of the blood which flows through the lungs is diverted before reaching the systemic capillaries and is recirculated through the pulmonary bed The volume of blood pumped through the pulmonary capillaries therefore exceeds the systemic flow per minute unless complicating shunts in the opposite direction are also present Pulmonic blood flows of 10 to 12 liters per minute with systemic flows of 2 to 3 liters per minute are common and the ratio

murs may be as loud as grade 4 but are not usually accompanied by a thrill When the pulmonary artery is greatly dilated there is sometimes an extra sound in early systole ("systolic click")

DIAGNOSTIC METHODS

Roentgenography The importance of roentgenographic examination in congenital heart disease can hardly be overstated Fluoroscopic examination should be carried out in every patient suspected of having a cardiac malformation and full size chest films in the posteroanterior and oblique positions with barium in the esophagus should be recorded The size and position of the great vessels and heart chambers the vascularity of the lung fields and the pulsations observed during fluoroscopy are often the deciding clues in differential diagnosis Characteristic configurations in some congenital anomalies of the heart are shown in Fig 163

Angiocardiography The introduction of radiopaque solutions into the blood stream to demonstrate the course of the blood and to outline the chambers of the heart is often of great help in diagnosis The extent of the information which can be obtained is determined largely by the technical excellence of the equipment used Angiocardiography is most helpful with complex malformations in which data from catheterization are inadequate or equivocal particularly when there is some uncertainty as to how blood reaches the lungs or which ventricle communicates with the systemic circulation

The contrast medium is usually introduced into a peripheral vein although injection directly into the heart through a cardiac catheter ("selective angiocardiography) has been used extensively in some centers Although intracardiac injection gives technically excellent films the associated morbidity and mortality are distinctly higher than with intravenous injection

In planning diagnostic studies on a patient it should be remembered th t the risk of angiocardiography using conventional intravenous injection is appreciably higher than that of right heart catheterization In a joint report by several medical centers in the United States the mortality in a series of 8 000 angiocardiograms was given as 0 3 per cent As with cardiac catheterization the hazard is greatest in the presence of pulmonary hypertension or cyanosis

Electrocardiography In congenital heart disease the principal contribution of electrocardiography is the determination of specific ventricular hypertrophy and it is often more sensitive for this purpose than roentgenography The characteristic changes with right left and combined ventricular hypertrophy are described in Chap 223 Right ventricular hypertrophy and enlargement are common with many types of congenital malformation and the QRS axis may show extreme degrees of right axis deviation In the most extreme examples of right ventricular hypertrophy the QRS axis may come to point over the right shoulder giving prominent S waves in standard lead III which may erroneously be interpreted as left axis deviation The amplitude of the QRS complexes is as important as the QRS axis in evaluating ventricular hypertrophy QRS changes are always more specific than T wave abnormalities in indicating which ventricle is involved

Prolongation of the QRS duration beyond 0 12 sec is *uncommon* in congenital heart disease An rsR complex in precordial lead V1 and adjacent leads occurs frequently with right ventricular hypertrophy but the duration usually ranges from 0 06 to 0 11 sec This pattern has been termed "incomplete right bundle branch block" when the QRS duration is from 0 10 to 0 12 sec but the clinical significance in this situation is the same as with shorter QRS durations The Wolff Parkinson White conduction anomaly is not common in congenital heart disease except in Ebstein s disease

Prolonged P R intervals are particularly frequent with atrial septal defect and are found occasionally in other malformations Complete atrioventricular block is rare Although it is said to be common in ventricular septal defects its incidence in this anomaly has probably been overestimated Congenital complete heart block is a rare functional abnormality which may occur in the absence of other defects and is usually of no functional consequence

Supraventricular arrhythmias including atrial fibrillation and flutter atrial and nodal tachycardia and wandering of the pacemaker occur with many malformations particularly with atrial septal defect and with Ebstein s disease Ventricular arrhythmias are no more frequent than in acquired heart disease

Cardiac Catheterization Information obtained by catheterization of the right side of the heart has been essential to the development of knowledge in the field of congenital heart disease In many cases it gives an accurate indication of the lesions present and a quantitative estimate of their functional significance

In general three questions can be answered by cardiac catheterization

1 Are the pres ures and pressure gradients in the heart and vessels normal? The most important deviations from normal pressure relationships to be recognized are elevation of right ventricular or pulmonary artery pressure or an exaggerated pressure drop across a valve indicating stenosis

2 Is highly oxygenated blood admixed with systemic venous blood at any point? The finding of

cial since the blood viscosity increases as the *hematocrit rises* The resulting increase in heart work is undesirable but of even greater significance is the tendency to vascular thromboses Hemiplegia and other cerebrovascular accidents occur frequently in polycythemic congenital heart disease as a result of cerebral thrombosis Dehydration is particularly to be avoided in these patients since further reduction of plasma volume increases the predisposition to thromboses In some patients with cyanotic congenital heart disease polycythemia is accompanied by thrombocytopenia and low blood fibrinogen levels leading to impaired clot retraction Severe postoperative bleeding following the surgical repair of congenital cardiac defects can sometimes be attributed to this deficiency

Clubbing Clubbing of the fingers and less often of the toes is usually found in patients who have had cyanosis and polycythemia over a period of years The pathogenesis of such clubbing is unexplained but it may represent excessive growth of local tissue due to increased blood flow Clinically identical clubbing may occur with pulmonary disease

Impaired growth Impaired growth and development in children has been attributed to tissue hypoxemia in venous arterial shunts but it is open to question whether such a causal relationship exists Some children with congenital heart disease are unquestionably stunted in growth and development while others develop normally Underdevelopment may be associated with malnutrition from inadequate feeding or with the frequent respiratory and other infections to which these children are prone or it may represent a concomitant congenital defect

Squatting Many patients with tetralogy of Fallot and some with other lesions which obstruct blood flow to the lungs find that squatting with the knees drawn up to the chest is the most comfortable resting position They are uncomfortable and often show increasing cyanosis if made to stand quietly or if they are tilted passively on the fluoroscope table Their avoidance of postures in which the legs are dependent suggests that decreased venous return is the important factor in these phenomena but the mechanism is not well understood Squatting is also observed in many normal children and is an habitual resting position of adults in many parts of the world The posture is clinically significant only if it can be shown to give symptomatic relief after exertion

Paradoxical Embolism This condition in which emboli arising in the systemic veins travel through a defect and lodge in a peripheral artery is always possible with right to left shunts This is probably responsible in part for the increased incidence of brain abscess in these patients

Pulmonary Hypertension

In the normal adult the pulmonary circulation is a relatively low pressure system mean pulmonary artery pressures of 15 mm Hg or less being sufficient to maintain adequate flow through the lung at rest Moreover the normal pulmonary vascular bed can distend sufficiently to allow at least a threefold increase in cardiac output on exertion with no increase in pulmonary artery pressure When a large left to right shunt exists in congenital heart disease so that a larger volume of blood flows through the lung than flows out of the aorta per minute the resistance of the pulmonary vascular bed gradually increases and the right ventricle must create a higher than normal pressure head to push an adequate volume of blood per minute through the lungs This increased pulmonary vascular resistance is partly reversible but pathologic studies show that definite anatomic narrowing of the pulmonary arterioles plays at least some part in its genesis Whether the vascular changes seen under the microscope are themselves congenital in origin or whether they represent an acquired response to chronically increased pulmonary flow remains open to question

It seems clear that the absolute magnitude of pulmonary blood flow is not the only factor which influences the development of pulmonary hypertension Abnormally high pulmonary artery pressures are found more often with ventricular than with atrial septal defects and only occasionally with patent ductus arteriosus although pulmonary blood flow is often three or more times the systemic flow in all these abnormalities

The most important practical effects of pulmonary hypertension are (1) *right ventricular hypertrophy* with characteristic effects on the roentgenogram and electrocardiogram If the strain on the right ventricle is too severe or prolonged failure may supervene with the same increased venous pressure distention of the liver and peripheral edema seen in right ventricular failure from other lesions (2) *Enlargement of the pulmonary conus and pulmonary artery* which can be recognized by fluoroscopy or roentgenography and may give rise to hoarseness by compression of the left recurrent laryngeal nerve between the aorta and the pulmonary artery Precordial pain spontaneous or on effort is frequently a troublesome symptom in patients with a dilated pulmonary artery and pulmonary hypertension

The principal physical signs of pulmonary hypertension are accentuation of the pulmonic second sound splitting of the second sound in the pulmonic area and a systolic murmur attributable to turbulence as the blood enters the relatively large volume of the dilated pulmonary artery Such mur

blood which is more highly oxygenated than samples taken further upstream (a "step up" in oxygen saturation) may indicate a left to right shunt through a defect but interpretation of such measurements is sometimes difficult As a result of incomplete mixing of the incoming streams from the superior and inferior venae cavae and from the coronary sinus which normally has a very low oxygen content there is a normal variation between samples from the same chamber which is almost always less than 2 0 vol per cent Differences of this magnitude or greater usually indicate a left to right shunt and in some circumstances differences of 1 5 vol per cent may be significant This significance is increased if confirmed by multiple samples It follows that small left to right shunts causing lesser differences in oxygen content (which would include most shunts equal to less than 25 per cent of the systemic blood flow) may not be detected by the *usual technique of the right heart catheterization* Right heart catheterization will not ordinarily identify the site of a right to left shunt unless the indicator dilution technique described below is employed

3 Does the catheter follow an abnormal course or pass through an abnormal opening? Under the fluoroscope the catheter may sometimes pass through a congenital defect and thus provide *prima facie* evidence of an anomalous communication Such observations must however be interpreted cautiously for the fluoroscopic image of the catheter in a single plane does not always identify its anatomic location unequivocally Moreover it is not always possible to put the catheter where one wants it In occasional patients for example repeated attempts to advance the catheter into the pulmonary artery will fail even in the absence of pulmonary stenosis or other abnormality Failure to pass the catheter through a suspected defect is therefore of little significance

Catheterization studies are usually done with the patient at rest under conditions approaching as nearly as possible a steady basal state Alterations in this steady state during the procedure which may change the relative oxygen saturation of consecutive blood samples are to be avoided

In many cases a reliable diagnosis can be reached on the basis of history physical examination and roentgenographic and electrocardiographic studies and cardiac catheterization is not needed Unnecessary catheterization is obviously to be avoided although the risk is small A mortality of 0 07 per cent was reported in a total of 5 700 catheterizations in eight laboratories in the United States The risk in acyanotic patients with moderate symptoms is distinctly less than this figure and most of the fatalities occur in severely ill patients with pulmonary hypertension and cyanosis The procedure is particularly hazardous in patients with primary pulmonary hypertension

Catheterization of the right side of the heart is indicated when data so obtained are essential to the management of the patient as for example in deciding on surgical treatment One hesitates to use cardiac catheterization when the diagnosis is already reasonably clear from routine examination and surgery seems not indicated but if the diagnosis is uncertain it is better to secure the additional information provided by cardiac catheterization than to deprive a patient of possible surgical benefit With more malformations being added constantly to the list of those amenable to surgery it becomes increasingly important to identify the lesions in each case of congenital heart disease by catheterization or other appropriate methods

Left heart catheterization via a direct needle puncture through the bronchus or through the thoracic wall has been employed by a number of investigators with encouraging results The risk of this procedure cannot yet be evaluated but is almost certainly higher than that of intravenous right heart catheterization Its eventual place as a diagnostic measure remains to be determined

Pressure measurements by direct puncture during open thoracotomy are now routine in many surgical departments and can give valuable data concerning the lesion and the immediate results of surgery It should be emphasized however that measurements obtained in the presence of the relatively low cardiac output systemic pressure and pulmonary artery pressure of the anesthetized patient with an open chest may be radically different from those under more normal conditions

Indicator-dilution Curves The arterial time concentration curve after intravenous injection of a dye or radioactive indicator is often characteristically modified by the presence of a shunt With right to left shunts an early curve is superimposed on the normal one and in left to right shunts the repeated recirculation of dye through the shunt and the lungs gives a typically low prolonged curve (Fig 165 p 1302) This method is not so sensitive in detecting small shunts as is catheterization but it can be used to identify the *site* of a right to left shunt if successive injections are made through a catheter at different locations Injections distal to the site of the shunt produce normal arterial curves while injections proximal to the shunt give typical right-to-left shunt curves Dilution curves are therefore useful as a screening procedure and as an adjunct to cardiac catheterization

Phonocardiography Careful investigation of heart sounds and murmurs by phonocardiography has elucidated many auscultatory phenomena and provided a number of useful diagnostic facts In practice however recording of the phonocardio

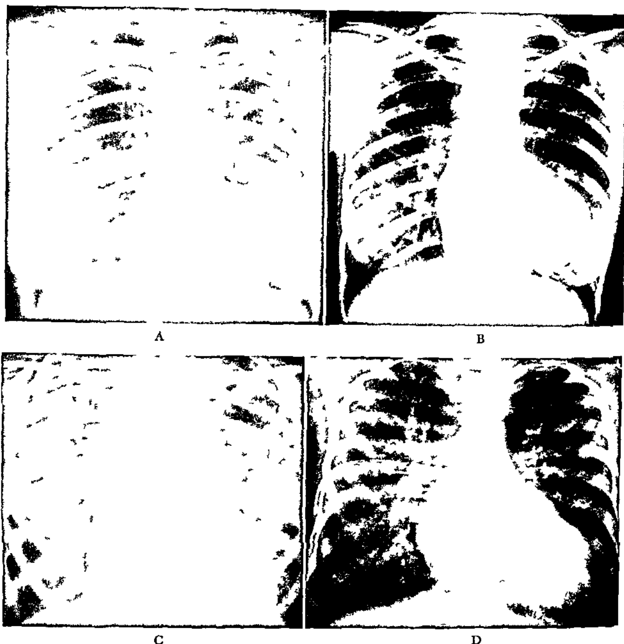

Fig 163 *A* Pure pulmonic stenosis with prominent poststenotic dilatation of the pulmonary artery in a 42 year old woman Pulmonary vascular markings in the peripheral lung fields are less prominent than in the normal person

B Tetralogy of Fallot in a girl 17 years of age Greatly increased transverse diameter with apex of the heart tipped up and relatively avascular lung fields (The three small radiopaque shadows at the upper margin of the film are artefacts)

C Anomalous drainage of all pulmonary veins into left innominate vein with typical figure 8 contour in a 4 year old boy

D Complete transposition of the great vessels in a 12 year old boy Note absence of normal pulmonary conus with narrowing of upper mediastinal shadow in this view prominent pulmonary vascular markings and ventricular enlargement

age ventricular septal defects and congenital stenosis of the mitral tricuspid and aortic valves These anomalies are enumerated in approximately the order of increasing operative risk which varies widely with the different lesions Closure of patent ductus arteriosus for example has been carried out in hundreds of patients since 1939 and the present operative mortality is about 2 per cent while open heart surgery on ventricular septal defect has been in use for a relatively short time and complete evaluation of the risks and results is not yet possible

The responsibility of deciding whether surgery is to be advised in an individual case should be shared by the internist and the surgeon The only rational basis for such a decision is accurate knowledge of the prognosis without operation in the case in question as compared with the risk and chances of benefit from surgery Under the best of conditions the factors which enter into this comparison are not as yet completely known

In general patients with physical signs of congenital heart disease but without symptoms clearly related to their heart disease should not undergo corrective surgery There are at least two exceptions to this generalization patent ductus arteriosus and coarctation of the aorta The chances of subacute bacterial endocarditis or other possibly fatal complications are so great with these two lesions that surgical correction should be considered in all affected patients under the age of thirty years even in the absence of symptoms

Patients with congenital malformations of the heart and symptoms which unmistakably limit their activity or give symptoms of increasing severity should be carefully studied as possible candidates for surgery

In estimating the severity of the burden imposed on the heart the patient s response to such ordinary activities as walking and climbing stairs is the best guide Dyspnea is a subjective phenomenon however and the patient s own estimate of his limitations may be misleading in either direction An objective test of myocardial competence in relation to ordinary activity is badly needed Measurement of cardiac output shunts and intracardiac pressure particularly under resting conditions do not sufficiently answer this need

In cases with severe and prolonged pulmonary hypertension the decision to operate is particularly difficult because some such patients have had no benefit or have died following technically successful correction of their defect Cases of patent ductus arteriosus with reversed flow (right to left) are the most striking examples of this dilemma Some such patients have been successfully treated surgically and no rule of thumb can be stated except to emphasize that patients who have developed sufficient pulmonary hypertension to reverse the direction of a shunt producing cyanosis even at rest are poor operative risks Prognosis for children with pulmonary hypertension following operation is better than that for adults in whom the inciting cause has existed for a longer period and the circulatory system is less adaptable

SPECIFIC MALFORMATIONS

Congenital heart disease includes such a variety of anatomic lesions and so many possible combinations of lesions that some system of classification is essential The classification most widely used at present based primarily on the presence or absence of cyanosis was introduced by Maude Abbott whose pioneer work in this field laid the foundation for much of modern knowledge

As useful as this system has been it has a number of disadvantages cyanosis is a subjective sign it occurs in a variety of lesions which have little else in common and it can be produced by at least three fundamentally different mechanisms (venous arterial shunt extreme peripheral desaturation inadequate pulmonary oxygenation)

A classification based on specific anatomic lesions rather than the clinical syndromes produced by combined lesions might be preferable The tetralogy of Fallot for example which is classed by Abbott as a cyanotic disease combines three specific lesions pulmonary stenosis overriding aorta and ventricular septal defect The clinical picture depends on the relative severity of these three malformations and usually includes decreased pulmonary blood flow and marked cyanosis If however the ventricular septal defect is large and the pulmonic stenosis and overriding of the aorta are mild in degree there may be increased pulmonary blood flow and no cyanosis

In the section which follows the Abbott classification has been modified and lesions are grouped according to their effect on blood flow as follows

I Malformations which permit shunting of blood
  A Initial shunt left to right
  B Initial shunt right to left
II Malformations which obstruct blood flow
III Malformations with no effect on blood flow

Class IA includes all lesions with an arteriovenous communication in which the normal pressure relationships after birth lead to a left to right shunt the potentially cyanotic group of Abbott The second subdivision *B* comprises Abbott s cyanotic group Class II includes most of the acyanotic" lesions of Abbott

Malformations with Potential Shunts

Initial Left to right Shunt *Atrial Septal Defect* This is the most common congenital lesion of the

gram is rarely necessary although it is helpful in occasional cases where the precise timing of an extra sound or the duration of a murmur is in question

COMPLICATIONS

In many types of congenital heart disease there appears to be a lowering of resistance to infections in general and to respiratory infections in particular A history of repeated attacks of bronchitis or pneumonia is common particularly in children and particularly with atrial septal defect In at least some cases malnutrition and underdevelopment may be ascribed to these recurrent illnesses Neither hypogammaglobulinemia nor deficient antibody formation seems to be concerned in this lowered resistance

Bacterial endocarditis acute or subacute is a common complication of congenital heart disease About 10 per cent of all cases of subacute bacterial endocarditis occur in congenital heart disease Patent ductus arteriosus ventricular septal defect coarctation of the aorta and bicuspid aortic valve are the lesions most likely to become infected while patients with atrial septal defect rarely develop this complication It may appear at any age but is commonest in young adults The symptoms signs and treatment of subacute bacterial endocarditis are the same with congenital heart disease as with other cardiac abnormalities Subacute bacterial endocarditis in patent ductus arteriosus is in itself an indication for surgical closure and this procedure alone will usually terminate the infection

Because of the susceptibility of many congenital cardiovascular malformations to bacterial endocarditis prophylactic antibiotic treatment should be *carried out during procedures which may produce* transient bacteremia such as dental extractions

Thromboses are common particularly in the cerebral circulation The high incidence in polycythemic patients and after dehydration suggests a relationship with blood viscosity Fluid intake should be carefully watched in such patients particularly in warm weather Cerebral thromboses may present with convulsions or sudden hemiplegia or they may be immediately fatal Treatment of the polycythemic patient is based on use of anticoagulant drugs venesection and hemodilution with intravenous isotonic fluids Continuous prophylaxis similar to that employed in rheumatic heart disease is not indicated however

Brain abscess is a serious complication of congenital heart disease which may appear any time after the first year or two of life It is more frequent in patients with right to left shunts since bacterial emboli by pass the lung filter and enter the brain Successful treatment depends largely on early diagnosis and the possibility of brain abscess should be considered promptly in any patient with congenital heart disease who develops unexplained fever headaches or other appropriate signs or symptoms

THERAPY

Medical Medical treatment of congenital heart disease consists mainly in the treatment of heart failure maintenance of myocardial compensation and prevention and treatment of complications

The congestive heart failure which occurs with congenital malformations of the heart does not differ essentially from that seen in other diseases of the heart and the principles of treatment are similar Digitalis is the keystone of therapy for establishing and maintaining cardiac compensation The choice of a digitalis preparation is dictated by the speed of action required and the personal prejudices of the individual physician There is no convincing evidence to show that the numerous digitalis preparations available differ in their clinical effects except in rapidity and duration of action

Many cases of congenital heart disease are instances of "high output failure" (see Chap 14) in the sense that at least one ventricle is required to pump more than its normal output per minute Digitalis is nevertheless just as effective in these cases as in the low output failure of most forms of acquired heart disease

In some situations myocardial failure eventually becomes intractable in spite of adequate digitalization and other therapy Acute left ventricular failure with pulmonary edema is treated with oxygen morphine tourniquets on the extremities elevation of the head of the bed and venesection (see Chap 226) In the polycythemic patient venesection *serves a double purpose by decreasing blood viscosity* as well as temporarily reducing total blood volume but it must nevertheless be used cautiously Right ventricular failure is more common than left in congenital heart disease and is usually a more chronic problem Salt restriction diuretics and the direct removal of fluid accumulations such as pleural effusions by thoracentesis are used to combat the tendency to retain water and salt

Digitalis toxicity is a frequent complication with consequences which can be as serious as those of the heart failure itself Frequent ventricular extrasystoles bigeminy and complete heart block are warning signs of digitalis overdosage which should be heeded

Surgical The congenital abnormalities which can be corrected or relieved by surgery at present comprise patent ductus arteriosus *pulmonary valvular* or infundibular stenosis (either isolated or in the tetralogy of Fallot) coarctation of the aorta atrial septal defect anomalous pulmonary venous drain

rection of the shunt may be reversed by complicating lesions such as an overriding aorta or by the gradual development of pulmonary hypertension Cases with extremely large defects or complete absence of the ventricular septum (single ventricle) are usually but not always cyanotic from birth

Symptoms in cases of isolated ventricular septal defect may appear in infancy or not at all depending on the size of the defect and the flow through it

A harsh systolic murmur of greatest intensity in the third and fourth interspace just left of the sternal edge is the classic sign of ventricular septal defect in the majority of cases it is accompanied by a thrill It usually extends throughout systole and is maximal in mid or late systole If pulmonary hypertension develops the systolic murmur decreases in intensity as the pulmonic second sound increases An apical diastolic murmur is present in most cases with large shunts

In the absence of symptoms the roentgenogram is often normal but may show increased pulmonary vascularity enlargement of both ventricles and often moderate left atrial enlargement The pulmonary artery and its branches are usually prominent and in patients with marked pulmonary hypertension may be greatly enlarged The electrocardiogram reflects whatever degree of combined right and left ventricular hypertrophy is present with normal axis or deviation to the right

Stenosis of the pulmonary valve or infundibulum may give a murmur similar to that of ventricular septal defect but it is usually loudest in the second or third interspace particularly with valvular stenosis The decreased pulmonary vascularity by x ray is the most important point in distinguishing these lesions from pure ventricular septal defect

The systolic murmur of atrial septal defect is occasionally quite loud and may even produce a thrill but it too is typically higher on the chest wall than in ventricular septal defect Moreover with atrial septal defect left ventricular hypertrophy does not occur unless mitral incompetence is also present In ventricular septal defect with marked pulmonary hypertension right ventricle enlargement predominates and differentiation from atrial septal defect by clinical means may be impossible Confusion may also arise in patients with mitral insufficiency where the murmur is more medial than usual but such a lesion produces left ventricular enlargement without right ventricular enlargement unless other valve lesions are present

Ventricular Septal Defect in Combination with Other Lesions Approximately 9 of every 10 patients with an interventricular septal defect also have other cardiac malformations of which the most common are pulmonary stenosis and overriding of the aorta Aortic incompetence due to an anomalous aortic cusp is an occasional complicating lesion of considerable importance because the murmurs and wide pulse pressure may lead to an erroneous diagnosis of patent ductus arteriosus

Eisenmenger's complex is the name of a condition in which there is a defect of the membranous ventricular septum with the relatively late appearance of cyanosis usually in adolescence Overriding of the aorta is regarded by some as an essential part of this syndrome but mild degrees of overriding are difficult to recognize even at autopsy and the diagnosis is based primarily on the clinical course Most patients designated as having Eisenmenger's complex probably have simple ventricular defects and gradually develop pulmonary hypertension with reversal of the shunt

Patent Ductus Arteriosus The ductus arteriosus which is an essential communication between the pulmonary artery and aorta during fetal development normally closes before the age of two years It may atrophy and disappear completely or persist as a solid cord.

Persistent patency of the ductus arteriosus beyond this age is a common abnormality representing approximately 10 per cent of all congenital malformations seen clinically The lumen varies from 5 to 10 mm in most patients With the normally existing pressure gradients there is a left to-right shunt from the aorta to the pulmonary artery but this varies greatly in magnitude in different patients and is often well tolerated The majority of patients with this anomaly are asymptomatic and are unaware of its existence until it is discovered on routine physical examination

The open ductus provides a low resistance pathway from the aorta during diastole as well as systole and a lowering of the arterial diastolic pressure results The arterial pulse pressure is thereby widened just as in aortic regurgitation

The left ventricle bears the burden of the shunt showing hypertrophy and enlargement in cases where the shunt is large enough to cause symptoms As in other left to right shunts continued high pulmonary blood flow is sometimes followed by the development of pulmonary hypertension This tends to decrease the left to right shunt and if the pulmonary artery pressure reaches systemic levels the flow through the ductus will be reversed with cyanosis of the toes and the area of the body nourished by branches of the aorta distal to the ductus In such cases cyanosis may appear at first only with exertion but if the patient survives the right-to-left shunt becomes permanent even at rest

When the ductus enters the aorta distal to the great vessels of the aortic arch as is customary a venous arterial shunt through it gives rise to the almost pathognomonic finding of cyanosis of the

heart The defects may be single or multiple and vary in size from an open foramen ovale to complete absence of the interatrial septum (cor triloculare biventriculare) Patency of the foramen ovale with an unsealed valve which persists in 5 to 20 per cent of the adult population becomes significant only if the pressure in the right atrium rises to a level higher than that in the left atrium causing a right to left shunt

Atrial septal defects may be divided into two general types *persistent ostium secundum* (cephalad or midseptal in location) and *persistent ostium primum* (caudad with one margin of the opening made up by the tissue between the atrioventricular valves) This distinction has a practical value for the surgeon since the persistent ostium primum is technically much more difficult to repair It also serves a clinical purpose in that the ostium primum type of defect is often accompanied by persistence of the atrioventricular cleft in the mitral and tricuspid leaflets which may cause clinically recognizable insufficiency of one valve or of both

In the normal person mean pressure is usually several millimeters of mercury higher in the left atrium than in the right When an atrial septal defect is present there is a predominant left to right shunt through it although streamlining of flow may produce a small right to left shunt as well If right ventricular resistance to filling increases as with the development of pulmonary hypertension or right ventricular failure the shunt may become predominantly right to left

The clinical effects of an atrial septal defect depend primarily on the size of the defect and the volume of the shunt through it An undetermined proportion of cases remain asymptomatic throughout adult life

In patients who develop symptoms the earliest complaints are exertional dyspnea and fatigue The gracile habitus shown by some children with this defect is relatively rare and the average patient shows normal growth and development unless there is an unusually large shunt Cyanosis and symptoms from pulmonary hypertension are not encountered until late in the disease if at all

A systolic murmur in the pulmonic area is the most prominent physical finding Its origin is not certain but most probably it arises from the increased flow through a normal pulmonic valve into a dilated pulmonary artery Flow through the defect itself apparently does not contribute to this murmur since it is often unchanged after surgical closure of the defect The second pulmonic sound is often widely split

Fluoroscopy shows a greatly enlarged pulmonary conus and pulmonary arteries increased pulmonary vascularity a "hilar dance" and enlargement of the right atrium and right ventricle The electrocardiogram shows signs of right ventricular hypertrophy in almost all symptomatic cases It has frequently been stated that the electrocardiogram in this malformation usually shows right bundle branch block but it is more accurate to say that an rsR pattern is often found in VI and other right precordial leads usually with a QRS duration less than 0 12 sec This rsR pattern in itself is probably an indication of right ventricular hypertrophy Paroxysmal atrial tachycardia atrial fibrillation and prolongation of the P R interval are all common

The above findings apply to the persistent ostium secundum type of defect and to those ostium primum defects in which the mitral valve functions normally In some cases a persistent ostium primum is complicated by severe regurgitation through one or both atrioventricular valves usually the mitral In these cases symptoms almost always appear in childhood and an apical systolic murmur plus radiologic and electrocardiographic signs of *left* ventricular hypertrophy as well as right reveal the mitral lesions Signs of free tricuspid insufficiency also favor the diagnosis of persistent ostium primum

Cardiac catheterization will usually establish the diagnosis subject to the general limitations of this procedure discussed above The differential diagnosis between atrial septal defect and anomalous pulmonary veins draining into the right atrium is often impossible

The majority of atrial septal defects are not complicated by other congenital lesions except for the tricuspid and mitral valve deformities mentioned The combination of atrial septal defect and mitral stenosis (Lutembacher's syndrome) appears to be much less common than previously supposed Modern diagnostic methods and surgical exploration have shown that an apical diastolic murmur is often present in cases of atrial septal defect when the mitral valve is entirely normal and the diagnosis of Lutembacher's syndrome should therefore be made with considerable caution

Ventricular Septal Defect This is the second most frequent congenital anomaly of the heart More than 90 per cent are defects of the membranous portion of the septum the remainder being in the muscular portion and usually unaccompanied by other cardiac malformations They vary in size from very small ventricular defects which produce a loud systolic murmur but no symptoms throughout adult life (*maladie de Roger*) to complete absence of the interventricular septum (*single ventricle cor triloculare biatriatum*)

In cases of *uncomplicated* ventricular septal defect the normally higher pressure in the left ventricle produces a left to right shunt but the di

anomalous drainage the pulmonic and systemic venous blood are mixed in the right atrium and pulmonary arterial and aortic blood are equally unsaturated Pulmonary artery pressure is usually normal or slightly elevated in occasional patients it may rise to a mean of 70 mm Hg or more

Cardiac catheterization can demonstrate the left to right shunt and step-up in oxygen saturation in the right atrial blood but cannot distinguish between anomalous pulmonary venous drainage into the right atrium and atrial septal defect unless the catheter actually passes out one of the pulmonary veins from the vena cava or the right atrium Even this finding is often equivocal since it is difficult to be sure that the catheter has not passed into normally draining pulmonary veins by way of an atrial septal defect The situation is further complicated by the frequent association of the two anomalies Angiocardiography can be helpful in demonstrating anomalous pulmonary veins draining into the venae cavae or coronary sinus but it does not rule out concomitant atrial septal defect In many cases therefore differential diagnosis of these two malformations can be made only at thoracotomy

When the anomalous veins drain only one lung a specialized application of the dye dilution method may establish the diagnosis Injection of dye or other indicator into first one and then the other main branch of the pulmonary artery will give a normal dilution curve in the systemic arteries after injection into the normally drained lung and a curve typical of a left to right shunt after injection into the anomalously drained pulmonary bed

As has been indicated many patients with partial anomalous pulmonary venous drainage are without symptoms and therapy is not needed In others however and particularly in the total anomalies signs of right heart failure develop because of a large shunt or pulmonary hypertension or both In these patients surgical intervention should be considered although with total anomalies and with marked pulmonary hypertension the risk of operation is high

Initial Right to-left Flow These are the cases of cyanotic congenital heart disease" in which the malformed structure of the heart and great vessels exposes the right ventricle to the systemic circulation from birth and the fetal predominance of the right ventricle therefore persists

The partitioning of the embryonic truncus arteriosus into pulmonic and aortic channels is a key stage in the development of the heart and anomalies in this process underlie a number of clinical malformations including complete transposition of the great vessels Fallot s tetralogy the Eisenmenger complex and some defects of the membranous portion of the interventricular septum An understanding of this episode in the development of the human fetus is essential to a logical appreciation of these lesions and the excellent reviews of Harris and Farber and Patten are recommended

Deviations in the location of the partitioning septum can produce great variations in the relative size of the aorta and pulmonary artery as in the very large pulmonary artery in Eisenmenger s complex Failure of the normal twisting of the truncus may leave the aorta in direct communication with the right ventricle only and the pulmonary artery with the left ventricle as in complete transposition The almost unlimited permutations and combinations of such developmental errors can lead to the most complex malformations

The caudad end of the truncus septum is contiguous with the membranous portion of the interventricular septum and with the edge of the interatrial septum which closes the ostium primum Any abnormality of development in this relatively small area in the fetus—an area perhaps 1 mm in diameter in the eight week old embryo—can give rise to such apparently diverse anomalies as transposed great vessels defects of the interatrial and interventricular septum and anomalies of the atrioventricular valves

Transposition of the Great Vessels In this malformation the failure of normal torsion of the primitive truncus leaves the aortic root opening into the right ventricle and the pulmonary artery into the left This separation of the pulmonic and systemic circulation into two independent circuits is obviously incompatible with life unless some additional anomaly provides a communication between them Complete transposition of aorta and pulmonary artery is therefore not seen clinically except in combination with other anomalies such as patent foramen ovale atrial septal defect ventricular septal defect or patent ductus arteriosus The bronchial arteries provide an additional shunt pathway in many cases The larger the communication the better the patient s chances for survival

In patients with these conditions the paths of blood flow are not yet fully understood but they involve mixed shunts which may reverse their direction from systole to diastole There is usually marked lowering of peripheral arterial saturation with cyanosis and polycythemia

Signs and symptoms including cyanosis are present from birth and rapid cardiac enlargement during the first year of life is the rule The malformation is occasionally seen in older children but the majority of the infants affected die during the first year unless compensating anomalies coexist

A precordial bulge is frequently present owing to the early cardiac enlargement and the precordial pulsation is indicative of dominant right ventricular enlargement The second pulmonic sound is

lower extremities with normally pink upper extremities Once this stage has been reached the prognosis is poor and survival for more than a year or two is exceptional

The classic murmur of patency of the ductus extends through systole and diastole as does the flow of blood through the ductus The murmur reaches its maximal intensity about the end of systole and overrides the second sound which may be completely obliterated It may begin with the first sound or in early systole and may extend throughout diastole or die away in late diastole The second left interspace at the sternal border is most often the area of maximal intensity The systolic element may be heard over most of the precordium and above the clavicles while the diastolic is sometimes less widely transmitted As in other left to right shunts a separate apical diastolic murmur from relative mitral stenosis is sometimes heard

Pulmonary hypertension modifies the typical murmur just as it modifies the size and direction of the shunt With roughly equal pressures in aorta and pulmonary artery and little or no shunt the murmur may disappear entirely while under other circumstances either the diastolic or the systolic component may be absent

Fluoroscopy may show a prominent pulmonary conus slight right and left ventricular enlargement slight increase in pulmonary vascularity or no abnormality at all The electrocardiogram may show moderate left or combined ventricular hypertrophy but is more often within normal limits

Patent ductus arteriosus can occur in combination with many other malformations In some instances such as complete pulmonary atresia a patent ductus performs an essential function by carrying blood to the lungs

Differential diagnosis is relatively easy in the average patient with a typical murmur and no cyanosis Although many other lesions produce both systolic and diastolic murmurs the two murmurs are usually separate and do not continue through the second sound Defects of the septum between the ascending aorta and pulmonary artery are an exception to this rule which is not surprising since this anomaly is physiologically identical with patent ductus except for the slightly more proximal site of the communication Cardiac catheterization may be of help in differentiating between patent ductus arteriosus and such aortic septal defects if the catheter passes through the defect Retrograde aortography may establish the diagnosis

Anomalous Pulmonary Venous Drainage This is a relatively uncommon malformation although its incidence is not accurately known A review of the literature in 1950 by Smith revealed only 133 published cases but increasing numbers of cases are being discovered by catheterization and surgery The most frequent sites of drainage are the superior vena cava the right atrium the left innominate vein and the coronary sinus The effects of this malformation depend on whether all or only part of the blood from the lungs is returned to the right heart Total anomalous pulmonary venous drainage requires an associated patent foramen ovale or atrial septal defect to allow blood to reach the systemic circulation while partial anomalous drainage in which some pulmonary veins enter the right side of the heart while others enter the left atrium normally may occur without other complicating lesions

Partial anomalies are often well tolerated and may be entirely asymptomatic while total anomalous drainage is a much more severe handicap less than a fifth of patients with the latter condition survive beyond infancy

In both situations there is a left to right shunt and therefore increased pulmonary blood flow but the size of the shunt varies greatly In patients with total anomalous pulmonary venous drainage there may be a history of cyanosis at birth and infancy and mild degrees of cyanosis at rest or on exertion and even clubbing in later life

Physical signs may be lacking in cases of partial anomalous pulmonary venous drainage but in the total anomalies there is almost always a grade 2 to 4 systolic murmur often with a thrill in the second to fourth intercostal space at the left sternal border This is probably related to an associated atrial septal defect and the accompanying dilatation of the pulmonary artery A softer continuous murmur is often heard in the aortic area probably a true venous hum from increased flow through the anomalous veins

Roentgenograms are characteristic in three specific patterns of anomalous pulmonary venous drainage (1) a common right pulmonary vein draining into the inferior vena cava which adds a smooth semicircular shadow to the right heart border (2) total pulmonary venous drainage into a persistent left superior vena cava giving a "figure 8 or "snowman contour to the whole cardiovascular silhouette (Fig 163C) (3) total pulmonary venous drainage into the coronary sinus in which the greatly dilated coronary sinus and anomalous veins displace the esophagus posteriorly simulating left atrial enlargement The electrocardiographic findings are normal in most asymptomatic patients and show signs of right ventricular hypertrophy as symptoms become predominant

Hemodynamically the systemic flow is normal or slightly lowered while the left to right shunt gives an increased pulmonary flow varying from one and one half to five or more times the systemic flow Peripheral arterial oxygen saturation may be normal with partial anomalies but with totally

anomalous drainage the pulmonic and systemic venous blood are mixed in the right atrium and pulmonary arterial and aortic blood are equally unsaturated Pulmonary artery pressure is usually normal or slightly elevated in occasional patients it may rise to a mean of 70 mm Hg or more

Cardiac catheterization can demonstrate the left to right shunt and step-up" in oxygen saturation in the right atrial blood but cannot distinguish between anomalous pulmonary venous drainage into the right atrium and atrial septal defect unless the catheter actually passes out one of the pulmonary veins from the vena cava or the right atrium Even this finding is often equivocal since it is difficult to be sure that the catheter has not passed into normally draining pulmonary veins by way of an atrial septal defect The situation is further complicated by the frequent association of the two anomalies Angiocardiography can be helpful in demonstrating anomalous pulmonary veins draining into the venae cavae or coronary sinus but it does not rule out concomitant atrial septal defect In many cases therefore differential diagnosis of these two malformations can be made only at thoracotomy

When the anomalous veins drain only one lung a specialized application of the dye dilution method may establish the diagnosis Injection of dye or other indicator into first one and then the other main branch of the pulmonary artery will give a normal dilution curve in the systemic arteries after injection into the normally drained lung and a curve typical of a left to-right shunt after injection into the anomalously drained pulmonary bed

As has been indicated many patients with partial anomalous pulmonary venous drainage are without symptoms and therapy is not needed In others however and particularly in the total anomalies signs of right heart failure develop because of a large shunt or pulmonary hypertension or both In these patients surgical intervention should be considered although with total anomalies and with marked pulmonary hypertension the risk of operation is high

Initial Right to-left Flow These are the cases of cyanotic congenital heart disease" in which the malformed structure of the heart and great vessels exposes the right ventricle to the systemic circulation from birth and the fetal predominance of the right ventricle therefore persists

The partitioning of the embryonic truncus arteriosus into pulmonic and aortic channels is a key stage in the development of the heart and anomalies in this process underlie a number of clinical malformations including complete transposition of the great vessels Fallot s tetralogy the Eisenmenger complex, and some defects of the membranous portion of the interventricular septum An understanding of this episode in the development of the human fetus is essential to a logical appreciation of these lesions and the excellent reviews of Harris and Farber and Patten are recommended

Deviations in the location of the partitioning septum can produce great variations in the relative size of the aorta and pulmonary artery as in the very large pulmonary artery in Eisenmenger s complex Failure of the normal twisting of the truncus may leave the aorta in direct communication with the right ventricle only and the pulmonary artery with the left ventricle as in complete transposition The almost unlimited permutations and combinations of such developmental errors can lead to the most complex malformations

The caudad end of the truncus septum is contiguous with the membranous portion of the interventricular septum and with the edge of the interatrial septum which closes the ostium primum Any abnormality of development in this relatively small area in the fetus—an area perhaps 1 mm in diameter in the eight week-old embryo—can give rise to such apparently diverse anomalies as transposed great vessels defects of the interatrial and interventricular septum and anomalies of the atrioventricular valves

Transposition of the Great Vessels In this malformation the failure of normal torsion of the primitive truncus leaves the aortic root opening into the right ventricle and the pulmonary artery into the left This separation of the pulmonic and systemic circulation into two independent circuits is obviously incompatible with life unless some additional anomaly provides a communication between them Complete transposition of aorta and pulmonary artery is therefore not seen clinically except in combination with other anomalies such as patent foramen ovale atrial septal defect, ventricular septal defect or patent ductus arteriosus The bronchial arteries provide an additional shunt pathway in many cases The larger the communication the better the patient s chances for survival

In patients with these conditions the paths of blood flow are not yet fully understood but they involve mixed shunts which may reverse their direction from systole to diastole There is usually marked lowering of peripheral arterial saturation with cyanosis and polycythemia

Signs and symptoms including cyanosis are present from birth and rapid cardiac enlargement during the first year of life is the rule The malformation is occasionally seen in older children but the majority of the infants affected die during the first year unless compensating anomalies coexist

A precordial bulge is frequently present owing to the early cardiac enlargement and the precordial pulsation is indicative of dominant right ventricular enlargement The second pulmonic sound is

greatly accentuated and not split Systolic murmurs and thrills are usually found but are related to the associated defects rather than to the transposition itself Some patients with a patent foramen ovale or patent ductus arteriosus have only faint systolic murmurs or none at all

The radiologic picture is often characteristic (see Fig 163D)

When the ascending aorta lies directly ventral to the pulmonary trunk their shadows are superimposed giving an unusually narrow upper mediastinal shadow and an absence of the usual pulmonary conus The pulmonary arteries and smaller vessels are large and pulsate vigorously Both ventricles and often both atria are enlarged Right axis deviation and marked right ventricular hypertrophy are found in the electrocardiogram

The diagnosis can usually be made from the history and roentgenologic features On cardiac catheterization the catheter may enter the aorta and the characteristically anterior origin of the aorta may be identified in the lateral view

A variant of this anomaly is complete transposition of the aorta with only partial transposition of the pulmonary artery so that the pulmonary artery overrides the right ventricle and a high ventricular septal defect (*Taussig Bing complex*) Although this malformation differs developmentally from the Eisenmenger complex the clinical pictures are similar The single distinguishing feature is the appearance of cyanosis at birth in the Taussig Bing complex as contrasted with its later appearance in the Eisenmenger complex

Persistent Truncus Arteriosus This is a rare anomaly in which blood flows from both ventricles into a single common trunk overriding a high ventricular ventral defect Blood reaches the lungs through pulmonary arteries branching from this trunk There may be a right or left aortic arch

Cyanosis is present but its degree depends on the relative proportions of pulmonary blood flow and venous arterial shunt Pulmonary blood flow exceeds normal values if there is free communication from the truncus to the lungs and no pulmonary vascular changes occur This increased pulmonary blood flow mixing with the systemic venous return often results in an almost normal oxygen content of arterial blood in spite of a large right to left shunt If two pulmonary arteries branch from the main trunk normal pulmonary blood flow obtains and cyanosis is minimal If only one small pulmonary artery leaves the truncus total pulmonary blood flow will be reduced If none of the pulmonary artery remnants communicates with the truncus directly the bronchial arteries may provide the only pathway for blood flow to the lungs Pulmonary blood flow is low and cyanosis is intense There is some confusion in the terminology applied to this condition which is sometimes termed "pseudo truncus Anatomically it more closely resembles tetralogy of Fallot than the usual truncus arteriosus

In infants the roentgenogram may be diagnostic with a sharp right angle between the shelflike upper surface of the right ventricle and the aorta in the left anterior oblique view With increasing age this disappears and the great right ventricular enlargement and absent pulmonary conus give a picture similar to that in Fallot s tetralogy

In *tetralogy of Fallot* the essential features are actually three in number pulmonary stenosis high ventricular septal defect and dextroposition of the aorta so that it overrides the defect The right ventricular hypertrophy which completes the tetralogy is a consequence of the abnormal hemodynamics induced by these three lesions

Fallot s tetralogy is the most common combination of lesions which leads to early cyanosis yet often allows survival into adult life The stenotic obstruction is usually in the infundibulum or right ventricular outflow tract, but may be in the valve itself or at both sites Dilatation of the pulmonary artery beyond the stenosis is usually not striking In some instances there is complete atresia of the pulmonary artery and blood reaches the lung through other channels a condition sometimes confusingly referred to as "pseudo truncus arteriosus" A large right to-left shunt is present with cyanosis appearing either at birth or within the first two years Clubbing and polycythemia follow at an early date The pulmonic stenosis produces a characteristic murmur described below and decreased pulmonary vascularity The electrocardiogram shows right ventricular hypertrophy The size of the heart radiologically is usually normal but the normal leftward convexity of the pulmonary conus is missing In some cases the apex of the heart is somewhat tipped up" in the anteroposterior view (see Fig 163B) A right aortic arch occurs in about 25 per cent of patients and can be seen to indent the barium filled esophagus to the *left* in the anteroposterior view and *posteriorly* in the left anterior oblique view

In rare cases usually in infants there may be only moderate pulmonic stenosis and a left to-right shunt Such cases of "atypical" or "acyanotic" tetralogy of Fallot have normal or increased pulmonary vascularity and diagnosis is often difficult

In the typical case the diagnosis can usually be made clinically These patients are more cyanotic than the usual case of uncomplicated pulmonic stenosis and do not have the greatly enlarged heart of complete transposition of the great vessels or the enlarged pulsating pulmonary artery of Eisenmenger s complex

Although many patients with tetralogy of Fallot reach adult life their exercise tolerance is invariably

limited and very few survive beyond the age of thirty years The Blalock Taussig operation provides an increased blood flow to the lungs through an artificial ductus relieving the cyanosis and clubbing and greatly increasing ability to exercise

Anomalous Origin of Coronary Arteries This is a rare malformation in which one coronary artery usually the left arises from the pulmonary artery A few cases with both coronary arteries arising from the pulmonary artery have been reported Although this must be classed as a right to left shunt strictly speaking its direct effects are limited to the heart muscle itself The combination of low coronary perfusion pressure and low oxygen tension seriously impairs myocardial function Severe congestive heart failure and cardiac enlargement appear in the first few months of life Pulmonary and peripheral edema may both develop The electrocardiogram shows ST and T wave abnormalities strikingly similar to those seen in adults with acute myocardial infarction (see Fig 164) Murmurs are usually absent Differentiation from other rare causes of early cardiac enlargement without cyanosis or murmurs discussed later in this chapter is based principally on the characteristic electrocardiographic changes

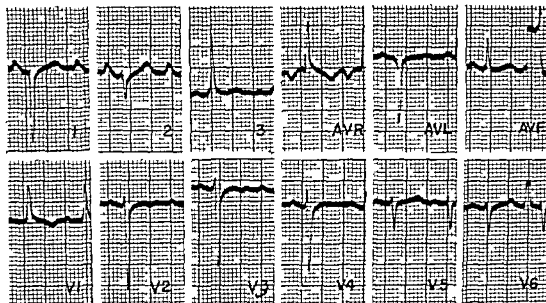
Malformations Which Obstruct Blood Flow

Pulmonary Stenosis This may involve either the pulmonic valve or the pulmonary infundibulum Since it is often associated with other anomalies the terms *pure* or *isolated* pulmonic stenosis are often used to indicate the absence of complicating lesions Cases of valvular stenosis with normal ventricular septum are much more common than previously thought and may constitute as much as 10 per cent of all patients with congenital heart disease The degree of stenosis varies from slight narrowing to a domelike membrane with only a pinhole opening

The principal effects of this lesion are reduction of the pulmonary blood flow and right ventricular hypertension and hypertrophy When the right ventricle can no longer maintain the high pressure needed to propel blood through the lungs congestive failure supervenes with the increased peripheral venous pressure hepatic distention and peripheral edema characteristic of right ventricular failure No shunt is present in uncomplicated cases but if the foramen ovale is unsealed and the pressure in the right atrium increases sufficiently a right to left shunt may result

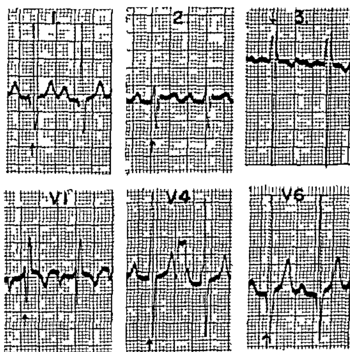
Patients with mild degrees of pulmonary stenosis may have no symptoms and have an excellent prognosis In more severe cases the age of onset of symptoms—primarily exertional dyspnea or syncope—and of cyanosis varies widely but in the average case is during adolescence With increasing age the proportion of patients with cyanosis increases Cyanosis is not invariably indicative of right to-left shunt in this anomaly for an appreciable number will show clinical cyanosis presumably of peripheral origin even while the arterial saturation is normal Exertional dyspnea usually precedes the appearance of cyanosis and for some time is more striking than the cyanosis Once cyanosis has appeared the course is usually progressively downhill but there are striking exceptions to this rule and occasional patients continue to exhibit cyanosis on exertion for 20 years or more with little change Clubbing is present in proportion to the severity and duration of cyanosis

The most important physical signs of pulmonic stenosis are a systolic murmur with maximal intensity (usually at least grade 4) in the pulmonic area and a diminished or absent second pulmonic sound Phonocardiograms reveal a splitting of the second sound but only the first (or aortic) component may be audible With infundibular stenosis the site of greatest intensity is somewhat lower in the third to fourth interspace at the left sternal border The murmur terminates before the second pulmonic sound Diastolic murmurs are not usually present a point which is helpful in differentiating this lesion from ventricular septal defect Signs of right ventricular failure including enlargement and sometimes pulsation of the liver develop in the most severe instances



Radiographic study shows a prominence or actual enlargement of the pulmonary artery and its main branches the so-called "poststenotic dilatation" (see Fig 163A) with valvular stenosis but usually not with infundibular stenosis The pulmonary arteries do not pulsate actively as a rule but with mild stenosis slight pulsation may occur The vascularity of the lungs is diminished giving a relatively clear appearance to the peripheral lung fields In mild cases the ventricles are of normal size while in severe cases the right ventricle may be enormously enlarged The right atrium usually enlarges along with the right ventricle

Electrocardiographic signs of right ventricular hypertrophy are usually in proportion to the severity of symptoms and moreover it is with this lesion that the most striking right axis shift and increase in the amplitude of the R wave over the right precordium (2 0 mv and more) are seen Right atrial enlargement is reflected by increase in the P wave amplitude most prominently in standard lead 2



The most important hemodynamic finding is an increase in right ventricular pressure and the demonstration of a large pressure gradient across the site of the stenosis Right ventricular systolic pressure in symptomatic patients is usually between 60 and 180 mm Hg but one patient with a pressure as high as 270 mm Hg has been reported The pres

sure drop across the stenosis is often 100 mm Hg or more The systemic flow is usually slightly below normal but not so much below as one would expect from the severity of symptoms One critical handicap in patients with this condition is their limited ability to increase pulmonary flow on exercise even with considerable increase in right ventricular pressure In extreme instances exertion may lead to syncope

Cases showing early cyanosis must be differentiated from tetralogy of Fallot and those with late onset of cyanosis from Eisenmenger's complex A

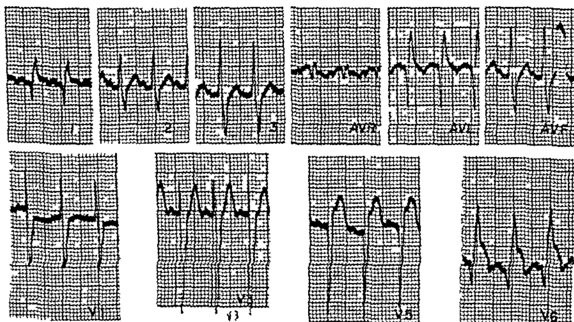
A

B

Fig 164 A Electrocardiogram from a 9 year old girl with pure pulmonic stenosis The right axis deviation in the limb leads tall R wave in lead V1 and reversal of the normal precordial transition indicate marked right ventricular hypertrophy Note that precordial leads were recorded at half normal sensitivity

B Electrocardiogram from a 5 year old boy with an atrial septal defect ("persistent ostium primum")

prominent pulmonary artery and marked dyspnea with relatively little cyanosis help to rule out tetralogy of Fallot, while clear lung fields and absence of pulmonary artery pulsation are not found in Eisenmenger's complex. Cardiac catheterization can furnish direct evidence of the stenosis and the degree of right ventricular hypertension. Accurate diagnosis is of particular importance because the Blalock-Taussig operation does not benefit patients with isolated pulmonic stenosis, the increased left to right shunt apparently being the last straw for an already overburdened right ventricle, which rapidly fails. The Brock procedure of pulmonary valvotomy is the treatment of choice.



Other malformations may be found in combination with pulmonic stenosis, including anomalous pulmonary veins, atrial or ventricular septal defects, and patent ductus arteriosus.

The prognosis is good in uncomplicated cases without cyanosis, cardiac enlargement, or electrocardiographic signs of right ventricular hypertrophy. When any of these findings is present with severe or increasing symptoms, surgical relief of the stenosis should be considered. In borderline cases the right ventricular systolic pressure is a useful guide to prognosis, and systolic pressures greater than 100 mm Hg are usually an indication for operation.

Coarctation of the Aorta. This obstructive lesion results from an abnormal obliteration of the aorta during regression of the multiple aortic arch system of the embryo. The common classifications are based largely upon the age at death (infantile and adult) and on the site of coarctation in relation to the ductus arteriosus. The infantile or preductal type occurs in the aortic arch or just proximal to the ductus arteriosus, which is usually patent. Commonly there are other intracardiac defects which account for death at an early age. In most instances blood from the pulmonary artery supplies the lower half of the body (through the ductus) and the toes are cyanotic often in contrast to the fingers.

Postductal or adult coarctation is usually located immediately distal to the left subclavian artery, and a narrowed or obliterated ductus enters the segment proximal to the coarctation. Bicuspid aortic valve is present in 25 to 40 per cent of cases, but otherwise the heart is normal. In rare instances coarctation may be in the midthoracic aorta, at the diaphragm, or even in the abdomen.

The presenting signs are hypertension in the arms

C

and cleft mitral leaflet producing mitral regurgitation. Combined right and left ventricular hypertrophy are indicated by the left axis deviation, tall R V1, and tall R V6. A double R wave is present in lead V1, with QRS duration of 0.09 sec, and the P-R interval is prolonged. (Arrows indicate the peak of R 1 and synchronous points in other leads.)

C. Electrocardiogram from a male child aged 4 months with anomalous origin of the left coronary artery from the pulmonary artery. The prominent Q wave and S-T elevation in leads 1, V5, and V6 are characteristic of anterior myocardial infarction.

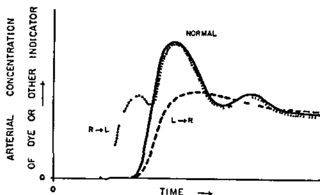


FIG 165 Schematic representation of arterial indicator dilution curve after intravenous injection of Evans blue dye or other indicator in normal persons (——) patients with right to left shunts ( ) and left to right shunts ( )

proximal to the obstruction and hypotension or absent pulses in the legs distal to it by these signs the diagnosis is made In the preductal type the associated intracardiac defects are prominent and incapacitating and the clinical picture is largely determined by these defects Patients with a postductal coarctation characteristically are troubled either early in life or a number of years later A few infants develop cardiac failure because of the load placed upon the left ventricle but most patients with coarctation of the aorta weather early childhood without symptoms or diagnosis Heart failure in an infant suggests some other lesion notably endocardial fibroelastosis for most infants with coarctation develop collateral circulation and hypertension is not striking until late childhood or adulthood Complaints rarely arise from diminished flow to the legs

In addition to the pathognomic pulse and pressure gradients there are striking pulsations in the neck and supraclavicular areas Systolic murmurs may be heard posteriorly from the coarctation or anteriorly from an abnormal aortic valve and diastolic murmurs may arise from collateral circulation Enlarged collateral vessels may be felt in the interscapular and subscapular areas

Notching of the ribs is the most characteristic radiologic observation caused by dilatation and tortuosity of intercostal arteries carrying the collateral flow A three sign may be produced in roentgenograms of the left upper mediastinum by the enlarged left subclavian artery the constriction at the coarctation and poststenotic dilatation distal to it

The electrocardiogram may be normal or may show left axis deviation and signs of left ventricular hypertrophy

In addition to cardiac failure most of these patients suffer from cerebral accidents rupture of the aorta or other complications of hypertension On occasion coarctation is associated with long life but 51 per cent of patients with this condition die before the fortieth year

The pathologic physiology has been of considerable interest because hypertension in this disease is associated with a discrete lesion which can be surgically corrected In addition to increased resistance from the constriction and the collateral vessels a renal mechanism activated by the lowered renal blood flow and pressure seems to contribute to this hypertension

Surgical correction is indicated in most children and also in adults in whom hypertension is great or symptoms related to it are present The segment can be excised and end to end suture performed in most instances but in some cases a graft may be required to bridge the gap or to obtain a satisfactory lumen

Stenosis or Atresia of Other Valves Congenital stenosis of the mitral tricuspid or aortic valves is uncommon Except for the relatively early appearance of signs and symptoms as compared with their counterparts in rheumatic heart disease the effects are similar *Tricuspid atresia* is usually associated with an underdeveloped or absent right ventricle atrial septal defect and atretic pulmonary artery Blood flows from the right into the left atrium and left ventricle and reaches the lungs through a patent ductus arteriosus The right ventricular cavity is absent or filled with blood clot or it communicates with the left ventricle through a ventricular septal defect but does not function Left axis deviation in the electrocardiogram results and this finding in a cyanotic patient is virtually pathognomonic of tricuspid atresia

Aortic atresia extremely rare is associated with a hypoplastic nonfunctioning left ventricle and frequently with *mitral atresia* as well Blood flows from left atrium to right atrium to the lungs and reaches the systemic circuit only through a patent ductus Survival for more than a few weeks is rare

Malformations without Direct Effect on Blood Flow

Dextrocardia and Situs Inversus Dextrocardia may occur as an exact mirror image reversal of the heart within the thorax (*true dextrocardia*) or as abnormal rotation of the heart with twisting of the great vessels (*dextroposition* or *dextrorotation*) of the heart Situs inversus or reversal of all the viscera may accompany any form of dextrocardia or it may occur with normal heart position Neither dextrocardia nor situs inversus is of any functional significance in itself but additional cardiac malformations are common and may be severe Mirror

image dextrocardia produces an almost pathognomonic electrocardiogram in the limb leads

Ebstein s Disease The rare anomaly of the tricuspid valve which bears this eponym consists of a congenital downward displacement of the valve into the right ventricle with anomalous insertion of one or more valve leaflets The malformation sometimes produces surprisingly little functional disturbance while in other cases incompetence of the tricuspid valve and impaired function of the right ventricle produce prominent signs at an early age Sudden death has often been reported

Although patients with Ebstein s disease are not cyanotic in infancy they may eventually develop right to left shunts through a patent foramen ovale The right atrium and right ventricle are then greatly enlarged and the pulmonary vascularity may be decreased The electrocardiogram shows tall P waves but no signs of ventricular hypertrophy Complete right bundle branch block and paroxysmal tachycardia are common There is often an apical systolic murmur which is attributed to incompetence of the dislocated tricuspid valve

Anomalies of the Aortic Arch The multiple bilateral aortic arches of the embryo provide a background for a great variety of anomalies One of the commonest is a *right aortic arch* in which the ascending aorta arches toward the right instead of the left The aorta may then continue to lie on the right in its descent or may cross over to descend in the normal position just left of the midline In either case the anomaly is of no functional significance A right aortic arch may be recognized by its indentation of the barium filled esophagus since it impinges on the *right* side of the esophagus in the anteroposterior view and displaces the esophagus backward in the left anterior oblique view

In some cases both right and left aortic arches persist forming a vascular ring Such a ring which may also result from anomalies of the subclavian or other arteries usually has no effect on cardiac function but it may produce symptoms by compression of the esophagus or trachea

Anomalies of the Great Veins Many variations in the structure of the superior and inferior venae cavae and their major branches are possible A persistent left superior vena cava for example is a fairly common anomaly Anomalous venae cavae may drain normally into the right atrium and be of no functional significance or they may drain into the left atrium producing major venous arterial shunts The course of such anomalies can usually be clearly outlined by angiocardiography

Congenital Cardiac Hypertrophy On rare occasions cardiac dilatation and hypertrophy with congestive heart failure develop during the first few months of life in the absence of cyanosis thrills or murmurs In a few of these cases no clear etiologic factors can be discovered even on pathologic examination and they are accurately termed *idiopathic congenital cardiac hypertrophy*

The same clinical picture may be produced by a variety of causes including endocardial fibroelastosis von Gierke s disease nonspecific myocarditis and prolonged ectopic tachycardia

Endocardial fibroelastosis is a collagenous and elastic tissue thickening of the endocardium lining the heart chambers most frequently limited to the left ventricle The etiology is not known fetal endocarditis has been suggested as a possible cause but the evidence is not convincing In some cases the cardiac enlargement is predominantly left ventricular while in others the endocardial sclerosis appears to constrict the left ventricle and lead to right ventricular hypertrophy

Von Gierke s disease is a general metabolic disorder in which glycogenolysis is impaired and intracellular deposits of glycogen are found in the liver kidneys and myocardium Hepatomegaly fasting hypoglycemia and ketonuria are characteristic features

The diagnosis of *nonspecific myocarditis* is based on the microscopic finding of interstitial round cell infiltration often with small areas of necrosis or fibrosis in the myocardium in the absence of infectious or other known causes of myocarditis

Prolonged paroxysms of tachycardia in infants have occasionally been reported as a cause of marked cardiac enlargement and death Although prominent dilatation of the ventricles can occur under these circumstances it is unlikely that myocardial hypertrophy can be attributed to a prolonged rapid heart rate alone

226 CONGESTIVE HEART FAILURE

T R Harrison and William H Resnik

The patient with cardiac disease may face any one of four major hazards or a combination of them These are (1) inadequate coronary circulation (2) bacterial endocarditis (3) embolic complications and (4) congestive failure The first three of these hazards are dealt with in Chaps 224 145 and 230 respectively and the present chapter is limited to the subject of congestive failure Since the basic mechanisms of congestive failure have been considered previously in Chap 14 the present discussion will deal chiefly with the clinical manifestations and treatment of this disorder Cardiac dyspnea produced by exertion acute pulmonary edema and chronic cardiac dropsy represent different types and stages of heart failure

EVOLUTION

The Senile Heart (Presbycardia) The reserve power of the youthful heart is very great There is ample evidence that the decline in strength which occurs in skeletal muscle as a person becomes older also takes place in cardiac muscle Cardiac output per minute and stroke volume decrease with age and circulation time increases Disorders known to place an unquestionable handicap on the heart may precipitate congestive failure in a patient forty five years of age or older even though the same burden may be tolerated without difficulty by a younger person Thus slight elevations of arterial pressure mild forms of thyrotoxicosis and paroxysmal tachycardia of relatively moderate duration may be associated with congestive failure in elderly persons although much more intense examples of the same disorders rarely bring about failure of the myocardium in young individuals The diminishing capacity of the myocardium to cope with these various burdens—organic metabolic or peripheral vascular—as the patient reaches the fifth or sixth decade of life is not due to a reduction in the blood supply to the myocardium when the coronary arterial system is not greatly involved Careful quantitative observations on the perfusibility of the aging heart have demonstrated that aside from diminution in the blood supply to the myocardium due to gross narrowing of the larger branches of the coronary system there is no reduction in the vascular bed that can afford a satisfactory basis for the congestive failure that may have been present during life

This loss of adaptive capacity of the aging myocardium is due to involutionary changes for which there is no recognized histologic basis and the biochemical defect is as yet unknown When these involutionary changes have progressed to the point where they cause or contribute in a significant degree to the appearance of heart failure the authors believe that the most appropriate designation for the condition is *the senile heart* which indicates the loss of cardiac reserve as the result of aging

When elderly persons dying of cardiac failure are found to exhibit lesions known to be well tolerated by younger persons it does not necessarily follow that these lesions *were the sole cause of* the heart failure ultimately causing death It is more likely that subtle senile changes superimposed on these various other lesions have converted them from tolerable into intolerable burdens on the heart *It is essential to appreciate the role that involutionary changes in the myocardium play in reducing the adaptive capacity of the aging heart in coping with the various handicaps to which it is subjected*

In a few elderly persons dying of congestive failure no significant cardiac lesions other than hypertrophy and dilatation are encountered at autopsy The coronary arteries display slight atheroma without narrowing myocardial scarring is minimal the valve cusps are normal Evidence of an extracardiac disease which might burden the heart such as thyrotoxicosis is also absent The blood pressure has been followed during life and has never displayed significant elevation In such persons it is likely that the involutionary process in the heart is the sole cause of failure The decline in reserve has become so great that even the normal load has been excessive Thus the *senile heart* has become so weakened that the patient has succumbed to *senile heart disease* More commonly however such a patient will be found to have coronary atherosclerosis In the absence of a history of anginal pain and of large myocardial scars one is uncertain even after autopsy about the relative importance of aging and of coronary disease in the production of the fatal heart failure

The concept of the senile heart was evolved by William Dock The authors consider it of fundamental importance in understanding many aspects of the problem of myocardial failure

Heart Failure with Effort *Manifestations and Diagnosis* The disproportion between myocardial strength and myocardial load leads to dyspnea, which ordinarily appears first during muscular exercise In a few patients undue fatigue is a striking manifestation but in most patients the complaint is that of increasing dyspnea for a given degree of exertion

The patient s age weight in relation to height and exercise habits must be evaluated before it is decided that the shortness of breath is anything other than a normal physiologic phenomenon Likewise the emotional status of the patient must be considered Worry about the presence of a minor valve lesion may lead to a sensation of smothering with the typical sighing which is so characteristic of the anxiety state

Even when an individual s shortness of breath is known to be beyond the physiologic limits it does not necessarily follow that cardiac disease is the cause Frequently emphysema advanced bronchitis or other pulmonary disorders are responsible Less commonly anemia or even general inanition with muscular weakness consequent to any grave constitutional disorder may lead to some shortness of breath The differential diagnosis of dyspnea has been discussed in some detail in Chap 10 but three points merit emphasis here (1) In deciding whether dyspnea is of cardiac origin the presence of clinical electrocardiographic or radiologic evidence of organic cardiac disease is important but not necessarily conclusive (2) The measurement of circulation time is a simple and valuable procedure With the exception of those disorders associated with increased cardiac output (Chap 14) cardiac dyspnea is associated with prolongation of the circulation time through the lungs On the contrary noncardiac dyspnea is usually associated with normal values for the circulation time. (3) In most borderline situations the response to a therapeutic test will supply conclusive information If the dyspnea is of cardiac origin the administration of digitalis and of a mercurial diuretic plus the ingestion of a salt poor diet will usually produce decisive benefit within 3 or 4 days The patient s subjective impression concerning his dyspnea should be supplemented by observation of the breathing after a given exercise and in doubtful instances by measurements of circulation time before and after the therapeutic test

Heart Failure at Rest *Manifestations and Diagnosis* After a period of months or years the patient with cardiac dyspnea tends to progress into a state of frank congestive heart failure (advanced heart failure) At this time symptoms begin to be present at rest In some instances these symptoms are related to congestion of the lungs alone and there is no evidence of systemic congestion The patient then has shortness of breath in the recumbent posture and frequently suffers from paroxysms of dyspnea (see discussion below under Acute Failure of the Left Side of the Heart) The evidences of cardiac enlargement are likely to be clearly apparent and gallop rhythm is the rule Rales at the lung bases will usually be found but their absence does not exclude the presence of left sided heart failure associated with congestion but without edema of the lungs Some patients display hydrothorax at this time but in most instances this complication occurs later as general anasarca begins to appear

The clinical picture of left sided failure is usually so distinctive as to offer little problem in diagnosis In doubtful instances measurement of the circulation time and observation of the response to digitalis will usually remove all doubt

Eventually the pattern of right sided heart failure develops In some instances this does not appear until the patient has already experienced the phenomena of left sided failure for some weeks or months However occasionally the two sides of the heart appear to fail at about the same time The usual signs of right sided failure are distention of the veins associated with increased venous pressure the presence of an enlarged tender and often painful liver edema albuminuria, and frequently cyanosis Hydrothorax is usually present when there is failure of both sides of the heart and is of great practical importance because of the relief that frequently follows removal of fluid Characteristically the right pleural cavity is affected more frequently than the left Some investigators have ascribed the greater frequency of right hydrothorax to anatomic features such as the position of the left auricle in relation to the two lungs or the right sided course of the azygos vein Others have been impressed by the tendency of patients with heart failure to lie on the right side more than on the left

Ascites is present in almost all instances of advanced right sided failure and under certain circumstances may be out of proportion to the fluid accumulation elsewhere This is seen frequently in children in patients with constrictive pericarditis and in patients with rheumatic disease affecting the tricuspid valve Patients with mitral stenosis may also exhibit prominent ascites with only slight edema of the legs This is probably to be ascribed to anatomic changes in the pulmonary arterial branches with secondary mechanical limitation of congestion and edema of the lungs Thus orthopnea is minimal and the effect of gravity on the distribution of dropsical fluid is less pronounced than in most instances of congestive failure

The clinical picture of a patient with right sided failure or with combined failure of the left and right sides of the heart is so characteristic that ordinarily there will be no difficulty in recognizing it

Other disorders such as cirrhosis of the liver and thrombosis of the hepatic veins (Chiari's syndrome) which may produce enlargement of the liver and ascites are not associated with elevation of venous pressure in the arms unless congestive failure is also present Obstruction of the superior cava may lead to striking distention of the veins of the neck and chest with edema of the upper part of the body However the evidences of collateral circulation are usually outspoken Edema due to renal disease to hepatic disorders or to rarer causes can usually be readily differentiated from the edema due to heart failure by the absence of venous distention of rales in the lung bases of orthopnea etc

In a few patients the pain consequent to hepatic congestion may lead to confusion with primary intraabdominal disorders This error can be avoided by a thorough examination of the circulatory system as well as of the abdomen

Many patients without cardiac failure display prominence of the cervical veins when recumbent Distention of these veins is indicative of increased venous pressure only when it is present in the sitting or semisitting position In doubtful instances the demonstration that compression of the upper abdomen causes marked distention of the cervical veins may be helpful Patients who are recovering from cardiac failure may not have elevation of venous pressure Likewise individuals in whom heart failure develops very suddenly without sufficient time for compensatory elevation of blood volume may have no measurable increase of venous pressure despite marked edema of the lungs In other patients with rapidly developing failure there may be distention of the central and cervical veins with collapse (or constriction) of the peripheral veins As a rule however this function is elevated in individuals with failure of the right side of the heart

Progression of Heart Failure The advance from the early stage with dyspnea only on effort to the full blown picture of combined left and right sided failure may occur gradually over a period of years even though there is no evidence of increasing load In such an instance loss of myocardial reserve as the result of the aging process is probably responsible More commonly however progression tends to occur in a jerky stepwise fashion rather than in a slow continuous evolution Anything which accelerates the heart rate or increases cardiac output is likely to precipitate the next stage of heart failure Thus any ectopic tachycardia may precipitate grave heart failure in a person with diminished cardiac reserve due to disease or age Also important are other causes of tachycardia such as fever from any cause respiratory infections with severe coughing excessive physical exertion prolonged and severe emotional stress anemia consequent to concurrent disease in other areas pregnancy and especially pulmonary infarction Another frequent aggravating cause of heart failure is the excessive ingestion of salt The prevention and management of these factors which constitute one of the most important general principles in the treatment of congestive failure are discussed later

COMMON CLINICAL PATTERNS

There are a number of situations in which the heart fails suddenly They include myocardial infarction fulminant myocarditis certain ectopic tachycardias and various rarer disorders These several types of acute cardiac failure are associated with evidence of minimal systemic congestion because they set in so rapidly that there is not time for compensatory increase in blood volume to occur Hence these conditions are likely to be characterized by a shift of blood from one portion of the circulation to another and in most instances the clinical picture mimics that of peripheral circulatory failure or shock the manifestations of congestion being limited to the pulmonary vascular bed This type of sudden cardiac failure has been discussed in Chap 14 and need not be considered further here However there is one form of acute heart failure which merits detailed discussion because of its frequency and of its response to therapy This is the condition known as *cardiac asthma* or *acute pulmonary edema*

Acute Failure of the Left Side of the Heart (Paroxysmal Nocturnal Dyspnea Cardiac Asthma and Acute Pulmonary Edema) Patients with hypertension with lesions of the aortic valve and with coronary sclerosis frequently are awakened by seizures of dyspnea Various names have been applied to these episodes The severe and fatal instances are characterized by acute edema of the lungs In many of the patients the moist rales are limited to the bases and the physical signs are chiefly those of bronchial obstruction with wheezes and rhonchi It is probable that edema of the bronchial walls is especially important here although some believe bronchospasm to be concerned When the number of moist rales is limited in relation to the wheezes and squeaks the condition may be confused with bronchial asthma or with other causes of wheezing Since the episodes usually occur at night the term *paroxysmal nocturnal dyspnea* has been widely employed but it has the disadvantage that similar episodes may occur during the day and that other diseases such as bronchial asthma occasionally cause paroxysmal dyspnea at night From the standpoint of tradition there is some advantage in retaining these several terms provided it is clearly understood that they all refer to one fundamental dis

order—acute failure of the left side of the heart

There is strong evidence that these seizures of dyspnea are usually precipitated by various conditions which lead to an increased return of blood to the heart Of particular importance are the recumbent posture and the associated reabsorption of extracellular fluid from the dependent portions of the body into the blood stream This leads to a situation analogous to that induced by the administration of saline solution to the patient Less important precipitating factors are cough nightmares excessive warmth and possibly abdominal distention Ordinarily they represent only the final straws which may awaken the patient or exaggerate the effects of the reabsorbed fluid

In a typical instance the patient who has previously had some shortness of breath on effort but no symptoms at rest retires for sleep in his usual state of health After an hour or more he is awakened with a sense of suffocation sits up and may seek an open window At the same time there is some coughing and examination of the lungs at this period will reveal a few moist rales at the bases and scattered squeaks over the lung fields In most instances the attack subsides after a few minutes of panting and coughing in the upright position However in the more severe attacks the dyspnea becomes progressively worse the cough more severe and there is expectoration of copious frothy sputum tinged with blood Examination reveals scattered wheezes and squeaks and in addition moist rales all over both lung fields This is acute pulmonary edema which may be fatal within an hour or two unless appropriate therapy is promptly instituted

Typically these seizures occur in patients with left ventricular failure due to hypertension lesions of the aortic valve or myocardial disease The first episode may be initiated by a myocardial infarction which may be painless In such instances the seizure is induced by sudden decrease in myocardial strength rather than by rapid increase in the load on the heart which is the more common mechanism

Attacks of dyspnea which awaken the patient from sleep are rather uncommon in patients with mitral stenosis except when precipitated by auricular fibrillation or pulmonary infarction However persons with mitral stenosis may suffer from acute pulmonary edema precipitated by exertion or even by recumbency In the latter instances the attacks usually begin before the onset of sleep

Patients with the milder episodes of acute left ventricular failure awaken assume the sitting or standing position and relieve the attack within a few minutes However the severe form of this syndrome represents one of the gravest of all medical emergencies Most patients with acute pulmonary edema will survive if therapy is prompt and vigorous Without such therapy many of them will die

Treatment The initial step should be the administration of morphine or an allied drug The benefit resulting from respiratory depressants is probably due to the effect of these drugs in breaking the vicious cycle whereby dyspnea itself a result of congestion of the lungs leads to reduction of mean intrathoracic pressure which causes greater inflow into the right ventricle and increase in the severity of the congestion when the left ventricle is less able to propel the blood offered to it Thus dyspnea causes more congestion which causes more dyspnea and so the vicious cycle proceeds until the respiration is depressed by a drug of the morphine group

Reduction of venous return to the right side of the heart can be accomplished to some extent by venostasis which consists in applying tourniquets to three extremities Every few minutes a tourniquet is placed on the fourth extremity and one of the others is released Thus the danger of thrombosis is minimized In the severer instances venesection should be employed and one should not hesitate to withdraw as much as a liter of blood in successive bleedings of 500 300 and 200 ml

Oxygen is urgently needed in patients with acute pulmonary edema Details concerning its administration are presented in Chap 273

When patients who have not received digitalis develop acute pulmonary edema the rapid acting digitalis preparations must be administered immediately Digitalis lanata (Cedilanid) should be given intravenously The total dose for a patient not previously receiving digitalis is usually 1 2 to 2 0 mg, which may be given over a period of 2 hr or less in urgent instances The initial dose should be 0 8 mg and subsequent doses of 0 4 mg may be given at half hourly intervals

When a patient has already been receiving digitalis the problem is more difficult Once it has been determined that the patient is only partially digitalized then Cedilanid should be used with caution in an initial dose of 0 4 mg followed by 0 2 mg at half hourly intervals until improvement occurs or evidence of digitalis intoxication appears

In the *prevention* of attacks of acute pulmonary edema the following principles of therapy are important (1) The maintenance of adequate digitalization (2) The treatment of extracellular fluid excess even though there may be no detectable pitting edema This involves the utilization of mercurial diuretics and restriction of sodium chloride (3) Every attempt should be made to avoid the precipitating factors A patient who has been having attacks of acute pulmonary edema should sleep in the semisitting position and should have a special bed when this is available Mild sedatives should be administered to minimize disturbing dreams Cough and emotional stresses should be

controlled so far as possible The evening meal should be small in order to minimize cardiac work When the condition recurs repeatedly a responsible member of the family should be instructed in the administration of morphine or an allied drug as soon as the attack begins Otherwise the patient may succumb before the physician can reach the bed side

To summarize attacks of pulmonary edema can be best prevented by vigilant and vigorous application of those therapeutic procedures which are used to treat heart failure in general and which are discussed later in more detail

Disorders other than left sided heart failure may cause acute pulmonary edema It may occur in patients with inspiratory obstruction presumably the lowered intrathoracic pressure favors transudation of fluid from capillaries into the alveoli If the obstruction is in the larynx tracheotomy may be of great benefit If the obstruction is lower in the bronchial tree bronchodilator drugs or antibiotics may be helpful depending on the cause

Pulmonary edema may be caused by inhalation of irritating gases or particulate matter Cessation of contact with the irritating agent is of course the first indication in management

Acute pulmonary edema may develop following severe brain injury e g in massive intracerebral or intraventricular hemorrhage or in bulbar poliomyelitis The mechanism is not well understood and little can be done to alleviate the situation

Oxygen therapy (p 1773) may be expected to be of assistance in any type of pulmonary edema where there is arterial unsaturation If equipment is available additional benefit may be obtained by administering the oxygen under positive pressure Agents which lower surface tension may be of value as adjuncts to oxygen in cases where there is a considerable quantity of foamy sputum The simplest method of achieving this is to bubble the oxygen through 95 per cent ethyl alcohol

Gravely ill comatose patients often exhibit coarse and rattling respiration This does not represent true pulmonary edema but instead is due to accumulation of mucus in the bronchi because of muscular weakness and depression of cough reflexes

Periodic Breathing In elderly persons with failure of the left side of the heart periodic breathing (Cheyne Stokes respiration) may be accompanied by recurrent brief episodes of dyspnea The same patient may have this periodic dyspnea as he dozes off to sleep and then be awakened by acute pulmonary edema More commonly a patient has only one of these syndromes The treatment of nocturnal dyspnea due to Cheyne Stokes respiration is essentially that of heart failure in general However opiates should be used sparingly and the milder sedatives are often efficacious This type of dyspnea usually indicates a poor prognosis but unlike acute pulmonary edema does not constitute a grave emergency

Chronic Congestive Heart Failure The majority of patients who have chronic heart failure have failure of both sides of the heart All the manifestations of both right and left sided failure are present in many patients but some of them present only a portion of these manifestations such as edema without detectable hepatic enlargement or the reverse situation Other patients will have right sided hydrothorax with no other evidences of failure of the right ventricle In such instances it is uncertain whether the accumulation of fluid in the pleural cavity comes from the visceral pleura and is a manifestation of left sided failure or whether it arises from the parietal pleura and is the result of early right sided failure The rarity of hydrothorax in patients with failure of one side of the heart only and its frequency when left and right failure coexist suggest that congestion of both parietal and visceral pleura may be necessary for its development

It should be emphasized that slight pitting of the ankles at the end of the day occurs in many healthy people Individuals who have lost weight frequently have a palpable liver Elderly persons who are leading a sedentary life are often short of breath on exertion Emotional disturbances may rarely cause episodes of shortness of breath (usually described as smothering) at night Thus there may be some doubt in a borderline situation as to whether a patient does or does not have cardiac failure In such an instance observation of the response to a mercurial diuretic and to digitalization will usually supply conclusive evidence When the symptoms mentioned are not due to cardiac disease little or no improvement will be noted and even this will be mainly the result of suggestion When however such apparently minor symptoms are in reality the earliest indication of myocardial failure the administration of digitalis to a patient who has not previously received it and of mercurial diuretics will usually result in such striking improvement as to remove all doubt from the physician s mind Actually in most instances such a therapeutic test is not necessary because the presence of a diastolic gallop will often settle the question conclusively However one should remember that the presence of objective evidence of cardiac disease such as an organic murmur or an unquestionable abnormality of the electrocardiogram does not necessarily mean that the symptoms are the *result of cardiac disease* Individuals with such minor cardiac abnormalities may have symptoms which are the result of coexistent emotional or physical disorders In such persons impressive re

sponses to digitalis and diuretics will not be observed

It should be emphasized again that the diagnosis of congestive failure must not be based on any one manifestation but rather on a combination of them Thus enlargement of the liver and ascites may be the result of cirrhosis and an almost identical picture may be caused by constrictive pericarditis In the latter instance there will be increased pressure in the cervical veins and in those of the upper extremities such manifestation being absent in patients with cirrhosis Likewise mediastinal tumors may be associated with increased pressure in the veins of the neck and of the arms but evidence of congestion in the lower part of the body will be absent

Edema due to renal disease is associated with characteristic changes in the urine The changes are either those of the nephrotic syndrome with massive albuminuria or of acute glomerular nephritis with hematuria and cellular casts Hypoproteinemia is frequently present in minimal degree in patients with chronic cardiac edema but rarely approaches the low values observed in patients with nephrosis and cirrhosis Patients with acute glomerulonephritis often have both cardiac and renal factors present and operative in the causation of edema The presence of dyspnea hypertension cardiac enlargement and gallop rhythm will usually be sufficient to indict the heart as one factor in the production of edema

Prognosis is uncertain in patients with chronic cardiac failure One cannot predict when massive pulmonary infarction a severe intercurrent infection or cerebral vascular complications will occur Despite such uncertainties three factors are of particular importance in prognosis The first is the response to therapy The failure of impressive improvement to set in within a few days following vigorous therapy is likely to indicate a grave outlook

The second factor is the type of underlying cardiac disease When the congestive failure is basically the result of a mechanical lesion such as tricuspid stenosis mitral stenosis or constrictive pericarditis the prognosis is likely to be much better than when the clinical manifestations are the result of a failing myocardium It is the latter which is responsible for heart failure in patients with coronary artery disease and in those with hypertension and aortic valvular disease Although these latter individuals have a mechanical burden symptoms do not occur until the left ventricular myocardium has lost its reserve On the other hand, the pulmonary manifestations of mitral stenosis are dependent on a purely mechanical disorder as are the systemic congestive manifestations of tricuspid stenosis Therefore patients with heart failure due to stenosis of the auriculoventricular valves may live for many years in a state of semiinvalidism This is rarely the case when as the result of disease or of the mechanical load the myocardium has to become defective before heart failure develops

A third important factor in prognosis is the evaluation of the circumstances under which heart failure develops When it has occurred as the result of some circumstance that is particularly amenable to treatment or correction such as auricular fibrillation with a rapid rate or respiratory infection or undue exertion or the excessive ingestion of salt the prognosis is likely to be much better than when heart failure has developed in the absence of any such additional stress In the final analysis however the response to treatment is the single most important point in prognosis

TREATMENT OF CHRONIC CONGESTIVE HEART FAILURE

Prevention and Management of Aggravating Factors The clinical state of patients with chronic cardiac disease does not progress steadily downward but tends to remain stationary or improve slightly for long periods of time with sudden worsening as the result of various complications Most of these complications are conditions which cause acceleration of the heart rate and/or increased output Ectopic tachycardias with extremely rapid rates may precipitate failure in individuals with previously good myocardial reserve However when the reserve power of the heart is much diminished even slight degrees of sinus tachycardia may exert deleterious effects Respiratory infections with the associated distressing cough physical exertion beyond that which produces dyspnea fever due to any cause emotional stress and anemia are particularly important in this respect The therapeutic implications are obvious

Pulmonary infarction discussed in Chap 236 is one of the commonest complications Its likelihood can be reduced by avoiding excessive rest in bed by permitting some slow walking by elastic bandages by alertness in the detection of phlebothrombosis and by the use of anticoagulants in appropriate instances

In patients with cardiac disease *pregnancy* involves a number of special problems which are discussed later

Rest and Activity The initial consideration in the management of the patient with congestive failure is that of placing him in a position in which dyspnea and the consequent metabolic demands on the heart are minimal In most patients the semirecumbent position in bed meets these requirements The upright posture favors edema formation in the dependent portions of the body but tends to diminish

pulmonary edema a far more serious condition than peripheral edema

Ordinarily the patient with congestive failure should be allowed to get out of bed and walk to a nearby commode for bowel movements This procedure has the additional advantage of tending to exercise the leg muscles and thereby reduce the likelihood of phlebothrombosis and pulmonary infarction When for any reason the patient s strength does not permit being out of bed and walking a little each day anticoagulant drugs elastic stockings and passive exercises of the legs plus massage are indicated

The great advantages of the recumbent position are in lessening fatigue and in combating peripheral edema and the subsequent rapid resorption of fluid during the night with the danger of inducing paroxysmal dyspnea Hence there is some advantage in attempting to induce diuresis by having the patient assume the horizontal position for several hours a day preferably in the late afternoon or early evening When this daily rest period induces diuresis it should be carried out indefinitely as long as the activities of the day in the upright position result in the development of more than a slight amount of edema of the lower extremities

Diet and Fluids All patients with heart failure should be placed on a low sodium diet the extent of the sodium restriction depending on the severity of the cardiac failure With the elimination of salted foods the use of sodium free milk bread and butter and the avoidance of canned vegetables and prepared condiments diets containing not more than 200 to 400 mg sodium per day can be administered At the same time it is important to be certain that the water ingested (especially if it is water that has been softened) is poor in sodium and that drugs containing sodium are avoided This extremely unpalatable type of diet is necessary only for patients with advanced heart failure In milder instances diets containing 1 0 to 2 0 Gm sodium (2 5 to 5 0 in salt) may be permitted

When the patient with congestive failure is first seen anorexia may be so severe as to preclude a reasonably well balanced diet Under these circumstances sodium free milk (Lanalac) or fruit juices alone containing only minute quantities of sodium are preferable to the traditional Karell diet (800 ml milk per day containing about 400 mg sodium) for the first 2 or 3 days At the end of this time and as the result of this regime and other therapeutic measures simultaneously instituted it is usually possible to administer a balanced diet containing not more than 200 to 400 mg sodium (equivalent to about 0 5 to 1 Gm sodium chloride) When compensation is fully restored or when the maximal therapeutic effect has been achieved some of the dietary restrictions may be lifted However it is preferable to insist that the patient remain permanently on a diet containing not more than 1 000 to 2 000 mg sodium and considerably less in the case of those individuals whose myocardial efficiency is markedly impaired The less the sodium intake the less the tendency for outspoken congestive failure to recur and the less the need for mercurial diuretics

The intake of water should usually be regulated by the desire of the patient

Weight reduction is desirable for obese patients and thiamine is indicated when there is protracted anorexia even of mild degree The other vitamins may be given also when the anorexia is both prolonged and severe

Digitalis Since this drug constitutes one of the cornerstones of management it will be discussed in some detail

Mode of Action The main effect of digitalis appears to be strengthening of the cardiac muscle with increase in ventricular emptying Thus the drug tends to overcome the cardinal hemodynamic defect of myocardial failure which is defective emptying of the ventricles (Chap 14) In patients with auricular fibrillation digitalis causes additional benefit by producing pronounced slowing of the ventricular rate by reducing the responsiveness of the junctional tissues to the barrage of impulses arising in the atrium The slowing of the rate is slight in patients with regular rhythm and appears to be of vagal origin

Indications Auricular fibrillation with a rapid ventricular rate constitutes one of the chief indications for digitalis When the drug is given intravenously as lanatoside C (Cedilanid) and when the arrhythmia is of the paroxysmal type and of short duration normal rate and rhythm are restored in some patients However this happens more frequently in patients with paroxysmal tachycardia *In chronic auricular fibrillation the drug slows the rate without abolishing the abnormal auricular rhythm* Digitalis frequently converts auricular flutter into auricular fibrillation Therapeutic doses will abolish premature beats in many patients with cardiac failure Toxic doses produce premature beats often in the form of bigeminal rhythm Further details concerning digitalis and arrhythmias will be found in Chap 223

The most common indication for digitalis is the presence of congestive heart failure even when the rhythm is regular When failure is severe the drug alone is often ineffective and other measures such as diuretics are needed However in the earlier instances and especially in those having attacks of paroxysmal nocturnal dyspnea digitalis alone is usually efficacious in treating and preventing the seizures

The drug should be used in patients with early

failure when the cardiac reserve is diminishing as indicated by increasing dyspnea for a given effort or by well marked gallop rhythm

In doubtful instances the value of the drug can be tested by clinical observation of the response supplemented at times by measurement of vital capacity and circulation time before and after digitalization This procedure is occasionally of value in differentiating dyspnea due to cardiac disease from that due to emphysema and other pulmonary disorders As a rule a patient should be given digitalis when the minimal exertion which can be carried on while leading a reasonably active life begins to induce dyspnea

Once digitalis has been administered for congestive failure the patient will usually need it either continuously or for long intervals throughout most of his life The practice frequently followed of discontinuing the drug as soon as the overt manifestations of congestive failure have disappeared is not sound

In some patients with paroxysmal auricular tachycardia the seizures are prevented by the daily administration of digitalis in other instances this procedure is ineffective

Contraindications This drug like any other is contraindicated under conditions where there is no clear indication for its use Neither enlargement nor murmurs constitutes an indication unless there is dyspnea or edema It should not be given to people with sinus tachycardia except when clear evidence of congestive failure either actual or imminent is present

Digitalis may cause nodal or ventricular tachycardia and most instances of fatal digitalis intoxication arise from the mistaken assumption that the presence of tachycardia in such patients constitutes an indication for larger doses Bradycardia of moderate degree is often a desirable effect and the common practice of discontinuing the drug when the heart rate is less than 70 per minute is unsound In some patients maximal benefit is achieved at rates between 50 and 60

Preparation and Dosage If one form of digitalis administered properly fails to produce improvement it is unlikely that significant benefit will be obtained by a different preparation The best results will usually be achieved by the physician who familiarizes himself thoroughly with only two preparations one a rapid acting type for emergencies and the other an intermediate or long acting product for long term digitalization

The idea that all patients require about the same dosage of digitalis is mistaken Actually there are wide variations The powdered leaf about 1 2 to 1 6 Gm in 48 hr and gitalin (Gitaligin) about 5 to 7 mg in 48 hr are excellent preparations for most patients who have not been previously receiving the drug When there is no emergency the best procedure is to give a patient about two thirds of the minimal digitalization dose in the first 24 hr If such a dose causes no improvement it is unlikely that digitalis will be of much value If the expected benefit has been achieved the maintenance dose may be instituted without proceeding to "full digitalization If the degree of improvement is less than anticipated the average maintenance dose may be given three times daily after meals for several days and then twice daily after meals The patient should be instructed not to take the drug unless the meal has been eaten and enjoyed In this way the onset of anorexia which is usually the initial manifestation of toxic effects tends to limit the dosage of the drug The usual daily maintenance dose is about 0 5 mg gitalin 0 1 mg digitoxin or 0 1 Gm powdered leaf

Many physicians prefer to use digitoxin because the available knowledge concerning its absorption excretion and destruction appears to be more precise than in the case of other preparations Such knowledge indicates that about one half the daily administered dose is excreted daily and that the destruction is largely independent of dosage and proceeds at a fixed rate for a given patient If the sum of excretion and destruction is greater or less than the daily intake the patient will eventually lose the digitalis effect or develop digitalis intoxication It is probable that the same principles apply to other digitalis preparations and if so it is theoretically impossible to maintain a patient in a properly digitalized state on a constant daily maintenance dose unless it is almost exactly equal to the sum of the daily excretion and destruction This dilemma may be avoided by routinely utilizing the average maintenance dose (Table 114) or slightly less of one of the intermediate preparations (digoxin or gitalin) and giving augmentation doses for a few days every 2 or 3 weeks At this time the patient must be seen by the physician in order to be certain that bigeminal rhythm and other manifestations of digitalis toxicity are not present In their absence the patient is instructed to take the previous daily maintenance dose three times daily after meals and only provided the appetite has not suddenly declined This procedure is continued until either (1) anorexia and/or nausea develops (2) the physician who should see the patient daily during this period of augmented dosage detects frequent premature beats or (3) the desired clinical improvement occurs In the latter instance there is no need to continue to the point of toxic effects Many patients do not require complete digitalization and will improve on this plan without untoward effects However if a constant daily dose of any preparation is employed indefinitely a large percentage of patients will

Table 114 DIGITALIS THERAPY

Preparation	Chief indication	Route of administration	Total dose for optimal initial effect	Optimal period for initial digitalization	Dissipation time		Usual maintenance dose	Remarks
					For toxic effects	For all effects		
Lanatoside C (Cedilanid)	Acute pulmonary edema myocardial infarction with failure	Intravenous or intramuscular	1 0–2 mg	2 12 h	1 day	4 7 days	Not employed	
Digoxin	Chronic heart failure	Oral	1 5– 5 mg	48 hr	3–4 days	6 8 days	0 5 mg	
Gitalin (Gitaligin)	Chronic heart failure	Oral	5–7 mg	2–5 days	1 3 days	5 10 days	0 5 mg	To arrive at full digitalization slowly use one-fourth optimal initial dose daily until desirable or toxic effects occur
Powdered leaf	Chronic heart failure	Oral	1 0–1 6 Gm	3–6 days	7 days	10 14 days	0 1 Gm	
Digitoxin	Chronic heart failure	Oral	1 0 1 6 mg	3–6 day	3 10 day	1 0 day	0 1 mg	
Acetylstrophanthidin *	To determine whether patient is digitalized *	Intravenous	0 2 mg every 5 min until toxic effects occur	Few minutes	Few minutes	2 hr		Appearance of toxic effects after 0 2 0 4 mg = preexisting digitalis intoxication 1 0 1 mg = not previously digitalized

* The use of this drug may be hazardous and its only value is in determining whether the patient needs additional digitalis In most instances this can be safely determined by omitting the drug for a few days.

eventually exhibit such effects or become completely undigitalized If this method is used the intermediate preparations are decidedly preferable both for maintenance and for augmentation because intoxication of mild degree frequently occurs during the periods of augmentation and the duration of such intoxication is less than when digitoxin or powdered leaf is employed

When a rapidly acting digitalis is desired or when one is uncertain as to whether or not the drug should be given and wishes to use a preparation the effect of which will wear off within a few days *Digitalis lanata* may be administered intravenously The most satisfactory preparation of *Digitalis lanata* is lanatoside C (Cedilanid) Its quick onset of action makes it especially valuable in the management of such emergencies as acute pulmonary edema Its rapid disappearance from the body makes it useful in patients who need digitalis but who are particularly susceptible to its untoward effects Hence in a person with myocardial infarction and increasing congestive failure in whom digitalization may precipitate a serious disturbance of rhythm this drug is preferable to powdered leaf or gitalin On the other hand the rapidity of elimination makes it less desirable for use in the management of the usual patient with congestive failure The usual total dose of lanatoside C required for digitalization is 1 to 2 mg for adults This is administered intravenously in divided doses over a period of 4 to 8 hr When good response is obtained a longer acting preparation should be used to maintain the effect Since lanatoside C is rapidly dissipated this can be accomplished by giving gitalin 0 5 mg three times daily after meals for about 5 days and then 0 5 mg once daily indefinitely The drug is temporarily *discontinued if the appetite is lost or nausea develops* In the above plan one may substitute 0 1 mg digitoxin or 0 1 Gm powdered leaf for 0 5 mg gitalin The administration of the longer acting preparation is begun about 8 to 12 hr after the final dose of Cedilanid

In patients who have been receiving digitalis and who have nausea and vomiting it may be difficult to decide whether these symptoms are the result of abdominal congestion and constitute an indication for additional digitalis or whether they represent *toxic effects from overdosage* Under such circumstances the use of acetylstrophanthidin has been proposed However this is a hazardous procedure In the usual patient the same information can be obtained by stopping digitalis therapy for a few days and noting whether the clinical state improves as will occur if digitalis intoxication has been present

In Table 114 the more pertinent information concerning a number of digitalis preparations is summarized

Manifestations of Digitalis Intoxication The most important of these include gastrointestinal disturbances—i e anorexia nausea and vomiting developing in that order—and disturbances of the

cardiac rhythm of which the frequent premature beat usually in the form of bigeminal rhythm is the most common Inversion of the T waves and slight increase in the P R interval are normal effects of the drug Severe degrees of heart block due to digitalis intoxication are exceptional in man although they occur frequently in animals when excessive doses are administered In an occasional patient the drug converts sinus rhythm into auricular fibrillation The reverse effect—conversion of auricular fibrillation to normal rhythm—may occur when the arrhythmia is of recent onset Nodal rhythm with moderate to marked tachycardia occasionally appears and ventricular tachycardia may develop with danger of ventricular fibrillation if the administration is continued Less common toxic effects include diarrhea and xanthopsia (yellow vision)

When doses within the therapeutic range are employed the only common toxic effects are anorexia nausea and bigeminal rhythm all of which disappear within a few days after withdrawal of the drug Since it is often desirable that the drug be pushed to the onset of the minor toxic effects it is well to warn the patient that vomiting may occur Such warning not only will alleviate anxiety if vomiting does appear but will make the patient more alert to report the onset of anorexia which is usually the initial and the most benign indication that the toxic effect has developed However it is important to remember that the more serious toxic effects may supervene without the preliminary appearance of the usual warning signals in the form of the milder manifestations of toxic action

Premature beats or other arrhythmias when induced by digitalis may be improved by the oral administration of potassium salts (Chap 223) Such arrhythmias are especially likely to be caused by digitalis when there is potassium depletion as the result of the frequent use of mercurial diuretics Since glucose ingestion causes decline in plasma potassium the toxic arrhythmias due to digitalis should be sought especially carefully during the period of 30 to 60 min after a carbohydrate rich meal When digitalis intoxication is present or imminent protein rich carbohydrate poor meals are indicated and potassium chloride (1 Gm three to six times daily) should be administered orally unless renal insufficiency is present

The most important principle of digitalis therapy is to push the drug until the patient exhibits either the desired therapeutic action or definite evidence of toxic effects This is only another way of saying what William Withering who introduced the drug into medical practice stated so clearly Let the medicine be continued until it either acts on the kidneys the stomach the pulse or the bowels let it be stopped upon the first appearance of any of these effects

Diuretic Drugs These are of great value All patients who have ever suffered from edema of cardiac origin and who have a tendency toward recurrence should weigh themselves each day under standard conditions As a rule this means weighing in the morning immediately after rising and emptying the bladder without clothing other than slippers and pajamas The written record of such daily weighings constitutes the guide to therapy by diuretic drugs

The mercurial diuretics are the most effective and their administration often results in striking improvement There is evidence that these drugs act by diminishing the reabsorption of chloride (and/or sodium) in the renal tubules such an effect being brought about by temporary depression of renal enzyme systems The volume of diuresis is usually greater if these drugs are given to patients who are concurrently receiving ammonium chloride 1 Gm (15 gr) three times daily The ammonium salts may produce acidosis if employed for more than a few days at a time Unless renal function is seriously impaired it is well to administer potassium chloride (3 to 4 Gm per day) routinely and to add ammonium chloride for 3 days when a mercurial diuretic is to be administered

Opinions differ concerning the mercurial diuretic of choice Convincing evidence that any one of the currently available preparations is superior to the others is lacking The size of the dose and the frequency of administration are governed by the severity of the congestive failure the rapidity with which its manifestations occur and the response in the individual case The initial dose should be 1 ml intramuscularly if no untoward symptoms are produced and a loss of 2 to 3 lb in the course of 24 hr is effected the same dose may be given daily for a few days or at longer intervals depending on the urgency of the case If a satisfactory diuresis is not produced by 1 ml 2 ml is given and this dose may be repeated after several days The mercurial is administered until all evidences of passive congestion have disappeared and the weight becomes stabilized at a steady level When compensation has been restored a maintenance dose of the mercurial is administered at varying intervals using the weight curve as the guide The patient should be instructed to report to the physician whenever the weight increases by as much as 5 lb within a period of 1 or 2 weeks or if a lesser gain in weight is attended by increase in dyspnea

The response to mercurial diuretics may be potentiated in some patients by administering am

nophylline intravenously (0 5 Gm over a 5 min period) 2 hr after the previous injection of the mercurial This synergistic effect is ascribed to the increase in glomerular filtration produced by the aminophylline while tubular reabsorption of chloride and of sodium is inhibited by the mercury compound

In many patients oral mercury is effective One to three tablets of chlormerodrin (Neohydrin) may be given after each meal Untoward effects may consist of gingivitis especially in patients with poor oral hygiene nausea and diarrhea Some patients respond well for many months but this is an expensive method of therapy

The untoward effects of mercurial diuretics fall into several categories the most important being those related to *electrolyte depletion* of different types These electrolyte disturbances are likely to occur in persons whose salt intake has been severely restricted and who have received vigorous mercurial therapy with massive diuresis Aside from refractoriness to further injections of mercurials there may be no symptoms or there may be a group of symptoms common to all regardless of the electrolyte patterns lassitude apathy mental confusion anorexia decrease in urine volume and azotemia When adequate facilities are available frequent measurement of the serum levels of sodium potassium chloride and carbon dioxide as well as of urea should be carried out especially when repeated injections of mercurials are necessary and when congestive failure does not respond to adequate therapy

The *low salt* or *salt depletion* syndrome is present when excessive sodium and chloride losses are disproportionately greater than those of water and when there is a corresponding lowering of these electrolytes in the serum When water sodium and chloride are excreted in excessive quantities and in ratios similar to those that obtain in the normal serum a volume deficit will ensue even though the plasma electrolyte pattern remains in the normal range and despite the persistence of edema in the dependent parts The treatment consists of the addition of salted foods or of salt rich bouillon to the diet or in more urgent cases by the slow infusion of 200 to 300 ml of 5 per cent sodium chloride on two or three successive days

The *salt dilution syndrome* presents the same electrolyte pattern with low sodium and chloride levels but this condition appears to develop through a different mechanism and to have a different significance It is encountered in the late stages of heart failure as well as in a variety of other unrelated terminal illnesses even when there have been no unusual losses of salt Hypertonic sodium chloride is rarely of benefit in these patients and although the plasma electrolyte pattern may be temporarily corrected thirst is aroused further excesses of water are retained the serum sodium and chloride levels fall to their previous levels and the net result is an increase in the extracellular fluid volume with further increase in edema Differentiation of the salt depletion from the salt dilution syndrome is sometimes difficult or impossible and the therapeutic test of the cautious administration of hypertonic sodium chloride may be required

Another important electrolyte disturbance stemming primarily from mercurial diuresis is *hypochloremic alkalosis* due to the disproportionate loss of chloride and potassium Body stores of potassium are usually depleted even though serum potassium may be normal Serum chloride is abnormally low bicarbonate is correspondingly elevated and sodium remains normal or at near normal levels Exactly the same chemical findings occur in respiratory acidosis and differentiation between the two must be made on clinical grounds unless means for accurate measurement of the plasma pH are available Respiratory acidosis occurs when the primary cause of the difficulty is a pulmonary disorder such as obstructive emphysema interfering with O_2 and CO_2 exchange or a depression of ventilation (e g morphine or sedatives) acting in essentially the same way The treatment of hypochloremic alkalosis consists of the administration of ammonium chloride 4 0 to 6 0 Gm per day in divided doses or when oral administration is not possible by the slow intravenous infusion of a 1 per cent solution of ammonium chloride at a rate not greater than 100 ml per hr Five hundred milliliters may be given on one day and repeated the next if necessary The effect of acetazoleamide (Diamox) is very similar to that of ammonium chloride and the combined effect of acetazoleamide 250 mg t i d and ammonium chloride 4 0 Gm per day may bring about a fairly rapid restoration of chloride to normal levels Potassium chloride 1 0 Gm four times daily should be given orally since a potassium deficit practically always accompanies hypochloremic alkalosis

Potassium deficiency in the absence of alkalosis may occur following the prolonged use of mercurials particularly when there have been additional losses of potassium by vomiting or diarrhea and when anorexia has limited the supply of food The chief manifestations in addition to those described above as being common to all electrolyte disturbances are unusual muscular weakness abdominal distention due to intestinal atony and electrocardiographic alterations progressive depression of the S T segment and rounding lowering and inversion of the T wave increasing amplitude of the U wave in the left precordial leads It is important to bear in

deficits may exist even though the serum potassium level may be normal and such a deficiency should be presumed to exist when ammonium chloride or acetazoleamide has been administered when hypochloremia alkalosis occurs and particularly when unexpected digitalis intoxication develops Consequently 2 or 3 Gm potassium chloride on the day of and the day following a mercurial injection may serve to prevent the appearance of potassium deficiency

Tetany due to loss of calcium is an uncommon complication of mercurial therapy

In patients with prostatic hypertrophy profuse diuresis following mercurial therapy may cause acute urinary retention

Intravenous administration of mercurial diuretics may lead to severe collapse and even to sudden death which is probably to be ascribed to interference with the normal role of sulfhydryl groups in myocardial enzymatic reactions Such very rare reactions do not follow administration by other routes Therefore the intravenous route should not be employed Allergic reactions are exceptional and may usually be prevented by change to a different preparation Acute anuria (lower nephron nephrosis) is very rare and can be largely prevented by measuring at frequent intervals the urea content of the blood and by careful clinical observations especially in relation to the early symptoms (lassitude apathy etc) of electrolyte depletion

Aside from the presence of evidence of the toxic effects which have been mentioned the chief contraindications to the use of mercurial diuretics are (1) failure of diuretic response to previous injection and (2) presence of serious impairment of renal function as indicated by marked elevation of blood urea by fixation of specific gravity of the urine or by the appearance of red blood corpuscles in the urine in large numbers A few red blood corpuscles do not constitute a contraindication nor does proteinuria

Refractoriness to mercurial diuretics represents a common and grave situation It can sometimes be overcome by the production of hyperchloremic acidosis For this purpose ammonium chloride (8 Gm daily in divided doses) is given for 5 days Unless the patient is eating normally potassium chloride (4 to 6 Gm daily) should likewise be prescribed During the first 3 days of the regime acetazoleamide is administered in doses of 250 mg twice daily On the fifth and several subsequent days mercurial diuretics are administered In doubtful instances blood chloride and carbon dioxide-combining power should be measured daily and the acetazoleamide and ammonium chloride administration continued until the respective values are significantly altered In some patients it appears to be necessary to achieve levels of 120 mEq per liter or more for chloride and 20 mEq per liter or less for bicarbonate before the refractoriness can be overcome

There are favorable reports concerning chlorothiazide (Diuril) a new orally effective nonmercurial diuretic Doses of 500 to 1 000 mg twice daily may be administered for several weeks if necessary Toxic effects are apparently minimal or absent while there is enhancement of excretion of sodium chloride and water

Other Therapeutic Measures *Sedatives* The judicious administration of sedatives is helpful especially in the early days of severe congestive failure For dyspnea morphine (10 to 20 mg) or Pantopon (10 to 20 mg) administered parenterally is usually effective in affording some degree of comfort and in ensuring sleep They are best given in the evening and after 4 hr or more repeated once during the night if necessary but always with due regard for the caution necessary in the use of these drugs in the aged and for the dangers of habituation if they are used for more than a few days Aside from promoting sleep opiates are valuable because they reduce the strenuous work of the respiratory muscles They also enable the subject to assume the recumbent position which often initiates diuresis After the first few days when congestive failure has been considerably alleviated moderate amounts of barbiturates may be substituted During the day small doses of phenobarbital (15 to 30 mg) two or three times daily may diminish undue restlessness and apprehension *It is most important however that one be particularly careful to avoid excessive sedation* because of the possibility of rendering the patient so lethargic that he is unwilling or unable to participate in sufficient activity to minimize the danger of phlebothrombosis and because of the undesirability of excessive respiratory depression in a patient with lowered vital capacity

Venesection Seizures of acute pulmonary edema constitute the most important indication for venesection which is a rapidly effective and often a lifesaving procedure under these circumstances (p 1307) Venesection is usually beneficial in patients with chronic cor pulmonale who have hematocrit values of 50 per cent or more Painful congestion of the liver may likewise be benefited Venesection may be employed in all patients with intractable heart failure but under such circumstances lasting benefit is rarely produced Ordinarily the amount of blood removed should be 300 to 500 ml for an adult patient of average size without anemia

Oxygen Administration of oxygen is indicated (1) in any patient with evidence of outspoken arterial hypoxia (2) when dyspnea is severe and possibly (3) in patients with intractable congestive failure When oxygen is needed for several days

a tent is the most useful method of administration for periods of a few hours a mask is convenient effective and relatively inexpensive (Chap 273)

Thoracentesis This is a valuable procedure in many patients with congestive failure It should be employed in all severely dyspneic patients who present evidence of hydrothorax which is frequently bilateral but often confined to the right pleural cavity *Abdominal paracentesis* is indicated whenever ascites is prominent and fails to respond promptly to sodium restriction and diuretics Massive hydropericardium is a rare complication but is of great practical importance and usually calls for paracentesis

Puncture of the Legs In some patients who respond poorly to diuretic measures edema may be overcome by puncturing the skin of each leg 10 or more times with an 18 gauge needle The patient should then remain in the sitting position for 12 hr or more and should be given appropriate antibiotics usually penicillin to prevent infection

Radioiodine Depression of the thyroid gland by the administration of radioiodine is sometimes of value in patients with intractable heart failure Such administration should be carried out only by someone with extensive experience in the use of radioisotopes The subsequent myxedema which may develop in about 3 months is likely to be sensitive to desiccated thyroid in unusually small doses even as little as 4 to 8 mg daily

Special Problems in the Management of Heart Failure *Pregnancy* The physiologic adjustments that normally take place during pregnancy the increase in heart rate cardiac output and blood volume place a burden on the cardiovascular system that reaches its peak at about the seventh or eighth month of pregnancy Thereafter these functions decline and tend to approach normality up to the time of labor This hyperkinetic state of the circulation acts to diminish the cardiac reserve a reduction of which is well tolerated by the pregnant woman with the normal heart but is tolerated with varying degrees of success by the woman with organic heart disease depending on the extent to which her cardiac reserve has already been diminished by the structural lesion of the heart *The greatest danger of congestive failure to the woman with heart disease occurs at the seventh or eighth month of pregnancy*

The increase in blood flow through the heart is frequently responsible for the appearance in normal persons of functional systolic murmurs which with the edema of the ankles that is also not uncommon and the displacement of the cardiac impulse by the elevated diaphragm and the resulting mistaken impression that there is cardiac enlargement sometimes may give rise to the erroneous idea that heart disease is present The increased blood flow also tends to accentuate murmurs in those who do have organic heart disease thus occasionally revealing for the first time a hitherto undetected lesion such as mitral stenosis Though there is no diminution in vital capacity ventilation increases and the respiratory reserve is curtailed thus facilitating the appearance of dyspnea with any given effort

The chief practical problems presented by pregnancy in relation to heart disease are as follows (1) Should the woman with cardiac disease become pregnant? (2) What should be done about a woman already pregnant who presents evidence of cardiac disease? In general these questions are answered by an assessment of the patient s functional capacity and this in turn is best determined by estimation of the symptoms caused by varying degrees of activity The patient who is asymptomatic or whose dyspnea is minimal even with strenuous exertion can undertake pregnancy with practically no more risk than can the woman with a normal heart On the other hand the presence of relatively severe symptoms with ordinary activity a history of hemoptysis (indicating the probability of an already significantly elevated left auricular and mean pulmonary capillary pressure) or a previous history of congestive failure make it inadvisable that pregnancy be undertaken and may indicate that the pregnancy should be terminated The same advice should be given if auricular fibrillation is present not because of the deleterious effects of the abnormal rhythm but rather because its presence indicates that an advanced stage of rheumatic heart disease is already present Nevertheless even auricular fibrillation is not an absolute contraindication to pregnancy or its continuation to term provided the functional capacity of the heart is deemed to be reasonably good the desire for the child great and the risks understood by the parents It is the intermediate group of patients those with symptoms on moderate activity who present the most difficult problem the decision depending on a multitude of factors aside from the status of the heart the number of children in the family the economic circumstances the opportunity for restriction of activity the likelihood that the patient will cooperate in reducing the preventable stresses on the heart the willingness to accept a calculated risk etc

Since the patient with heart disease starts out with the handicap of a diminished cardiac reserve which is still further lessened by the normal physiologic adjustments of pregnancy all other stresses that confer additional burdens on the heart and circulation require meticulous attention avoidance of overexertion and emotional tension correction

of anemia careful supervision of even minor in fections correction of obesity restriction of salt intake prompt treatment of abnormal rhythms especially tachycardias and frequent search by the physician for early signs of pulmonary con gestion

TERMINATION OF PREGNANCY If the patient is already pregnant and falls into one of the unfavora ble categories or if manifestations of congestive failure appear early termination by the vaginal route should be carried out during the first trimester After this time disposition of the patient is a matter of judgment and always entails uncertainty and risk If the symptoms are mild or moderate the patient may with careful medical supervision be carried beyond the critical seventh or eighth month after which the danger diminishes On the other hand if the symptoms are severe termination of the pregnancy may be considered imperative the method being left to the obstetrician

Once the patient has arrived at term the route of delivery should be decided by the obstetrician on obstetrical grounds Usually spontaneous de livery aided by low forceps is preferable Resort to cesarean section as a routine measure is no longer considered desirable this mode of delivery being reserved only for women who are expected to face a difficult and exhausting labor

The above comments are applicable in a general way to all women with heart disease but they refer particularly to women with rheumatic heart disease and mitral stenosis since they constitute the bulk of those with heart disease in pregnancy Mitral commissurotomy has been successfully employed in some women in whom threatening symptoms have appeared during pregnancy It is generally believed however that medical supervision alone or termination of the pregnancy is preferable opera tive dilatation of the valve being reserved for a later time when the patient is not pregnant Usually pregnancy in the patient with acyanotic congenital heart disease is well tolerated Repair of coarctation of the aorta should be done prior to pregnancy The occasional development of dissecting aneurysm during pregnancy or of a cerebral vascular accident during delivery makes this condition somewhat more hazardous than other asymptomatic cardiac disorders Advice regarding future pregnancies will depend on the course of the preceding ones and on the state of the heart at the time the next preg nancy is contemplated

Intractable Heart Failure From time to time physicians encounter patients with cardiac failure who either do not show a satisfactory initial re sponse to therapy or who having previously re sponded well become progressively more refractory to management Under these circumstances the physician will do well to ask himself the following questions (1) Is the therapy adequate? (2) Is there in this patient an unrecognized etiologic factor which might be treated successfully? (3) Is some complication making the patient respond so poorly? (4) Is the intractable heart failure due to extreme myocardial impairment? These questions will now be considered in some detail

1 *Has the patient received adequate therapy for congestive heart failure*? Is the dose of digitalis properly adjusted? If the patient has been receiving a maintenance dose of less than 0 1 Gm of the powdered leaf or 0 1 mg digitoxin, there is a defi nite possibility that he has escaped digitalization because the combined effects of excretion and de struction of the drug have exceeded the daily maintenance dose Under these circumstances it is frequently desirable to administer for a few days one of the intermediate preparations such as gitalin or digoxin in a dose equal to two or three times the average maintenance of such a preparation (see p 1311 and Table 114 p 1312)

Digitalis intoxication is likewise a common cause of what may appear to be intractable heart failure The presence of undoubted signs of such intoxica tion in an individual who has been receiving a relatively small maintenance dose makes it highly probable that potassium deficit has occurred as the result of anorexia and the frequent administra tion of mercurial diuretics Under such circum stances rapid improvement may follow the adminis tration of potassium chloride 3 to 6 Gm daily in divided doses for a few days If the maintenance dose of digitalis has been relatively large then the patient may be suffering from digitalis intoxication even though there is no potassium deficit Careful inquiry should be made concerning the presence of anorexia nausea and arrhythmias due to digi talis and the less frequent and less obvious mani festations of digitalis intoxication such as blurring of vision and xanthopsia should be sought If the patient has been receiving one of the intermediate drugs the manifestations of digitalis intoxication will disappear within 3 to 6 days after withholding it If powdered leaf or digitoxin has been employed improvement may be delayed for as long as 1 to 2 weeks after discontinuing digitalis

Defective restriction of sodium is another com mon cause of apparent intractability A patient may religiously refrain from adding salt at the table or during cooking and yet fail to realize that the bread he eats and the water he drinks may be excessively rich in sodium The physician should be familiar with the sodium content of the tap water in his community and should prescribe dis tilled water whenever necessary Sodium free bread is now available at most large grocery stores

One of the commonest causes of refractory heart failure is the presence of an electrolyte disturbance These disorders have been considered above

2 *Is there an unrecognized etiologic factor which might be successfully treated?* One thinks first of all of masked thyrotoxicosis This condition may present none of its usual clinical manifestations when occurring in an elderly patient with congestive heart failure One should entertain a high degree of suspicion toward such physical signs as unusual softness of the skin excessive sweating frequent bowel movements heat intolerance unexplained tachycardia etc Even with a high index of clinical suspicion patients with thyrotoxicosis will be overlooked unless one makes it a rule to determine the protein bound iodine of the serum in all patients with congestive failure

Chronic arterial hypoxia due to primary disorders of the lung is frequently complicated by congestive heart failure and may be strikingly benefited by oxygen therapy properly administered Anemia of clinically significant degree is usually obvious upon inspection of the patient s skin and mucous membranes but it may be overlooked The possibility of thiamine deficiency due to the long standing anorexia induced by abdominal congestion should be considered in every patient with congestive heart failure The suspicion should be particularly strong when treating elderly males who live alone or individuals who partake freely of alcohol In the younger group of patients with valvular disease the possibility that smoldering rheumatic myocarditis or bacterial endocarditis is present should be kept constantly in mind

It is perhaps even more important to look for evidences of those types of cardiac disease which are particularly amenable to surgical management *Mitral stenosis may be readily overlooked in a* middle aged or elderly patient with auricular fibrillation The presence of obvious congestive failure may keep the physician from a careful search for such congenital disorders as coarctation of the aorta and patent ductus with a systolic murmur only Constrictive pericarditis is especially likely to be missed unless careful precordial palpation and fluoroscopic examination are carried out on every patient with congestive heart failure

3 *Is there a hitherto unsuspected complication?* In patients who have been subjected to repeated mercurial diuretics plus a long standing low salt diet and more particularly if anorexia has been an important symptom one should be on constant watch for those electrolyte disturbances already discussed They are likely to manifest themselves by the relatively rapid onset of refractoriness to mercurial diuretics and by the simultaneous appearance of marked lassitude and apathy The recognition of hypochloremic alkalosis of potassium deficit of sodium depletion of the salt depletion syndrome or a combination of these disorders should be made according to the criteria described above In the absence of some serious primary disease of the kidney or of some obvious grave intercurrent disorder the presence of refractoriness to mercurial diuretics constitutes strong evidence for the presence of one of these electrolyte disturbances

Advanced renal disease frequently is present in patients with congestive failure and especially in those who have either hypertension or bacterial endocarditis During the initial phase of management the manifestations of congestive failure may overshadow those of the less obvious but often more serious renal disease The coexistence of nitrogen retention and of a urine of low specific gravity despite a small urine volume makes it highly probable that there is grave functional impairment of the kidneys and that the management of the cardiac failure and more particularly of electrolyte disturbances will be relatively unsuccessful

Pulmonary infarction discussed in Chap 236 is one of the commonest causes of intractable heart failure If this complication is recognized and vigorously treated either with anticoagulants or in suitable cases by venous ligation the heart may again respond to treatment after a period of days or weeks has elapsed In many instances the expected manifestations (pleural pain hemoptysis and changes in the x ray) will be absent and the sole clues to pulmonary infarction may be unexplained elevations of temperature leukocyte count or sedimentation rate plus aggravation of the cardiac status and at times an evanescent increase *in the serum bilirubin values*

4 *Is the intractable heart failure due to extreme myocardial impairment?* This suspicion should be entertained seriously only after the problem has been approached from the standpoint of the questions above Once one is satisfied that the therapy is entirely adequate that there is no complicating unrecognized etiologic factor and no serious complication one is justified in entertaining the question of myocardial disease so advanced that the heart failure has become and will remain intractable Under such conditions the patient has little to lose by receiving radioactive iodine and he may receive some benefit from it

B DISEASES OF THE VASCULAR SYSTEM

227 HYPERTENSIVE VASCULAR DISEASE

John P Merrill

Arterial hypertension in man may be arbitrarily divided into two categories pulmonary hypertension and systemic hypertension (Table 115) The more important problems related to pulmonary hypertension have been considered in Chap 224

Systemic hypertension is the manifestation of an abnormal state of the circulation just as fever is a sign of altered temperature regulation The word *hypertension* in itself implies nothing as to the associated prognosis or organic vascular or renal disease Indeed the role of elevated blood pressure in the production of aggravation of vascular disease is a disputed but important association which will be discussed separately As a clinical phenomenon hypertension may be diagnosed if on repeated examinations the blood pressure is found to be above that considered normal for adolescents of similar racial and environmental background In North American adults 140/90 may be regarded as abnormally high arterial pressure for coolies in Peiping 125/80 might have a similar significance

It is now apparent that the hypertensive syndrome has no single clear cut etiology Many factors are involved some of which may be thought of as mere exaggerations of the physiologic mechanisms by which normal arterial pressure is maintained Others are obviously abnormal in the sense that they play little or no role in normal circulatory regulation and are prominent only in disease states Any or all of these factors may be involved in any given case of hypertension It is not surprising therefore that in spite of a vast amount of interest and work no single therapeutic agent for the treatment of hypertension has come to light The physician or student who undertakes to study or treat hypertension must seek to understand the various mechanisms which may be involved when he attempts to evaluate their importance in the individual problem

FACTORS DETERMINING BLOOD PRESSURE

Blood flow through the normal vascular bed may be thought of as a system in which pulsatile flow

One of the commonest causes of refractory heart failure is the presence of an electrolyte disturbance These disorders have been considered above

2 *Is there an unrecognized etiologic factor which might be successfully treated?* One thinks first of all of masked thyrotoxicosis This condition may present none of its usual clinical manifestations when occurring in an elderly patient with congestive heart failure One should entertain a high degree of suspicion toward such physical signs as unusual softness of the skin excessive sweating frequent bowel movements heat intolerance unexplained tachycardia etc Even with a high index of clinical suspicion patients with thyrotoxicosis will be over looked unless one makes it a rule to determine the protein bound iodine of the serum in all patients with congestive failure

Chronic arterial hypoxia due to primary disorders of the lung is frequently complicated by congestive heart failure and may be strikingly benefited by oxygen therapy properly administered Anemia of clinically significant degree is usually obvious upon inspection of the patient s skin and mucous mem branes but it may be overlooked The possibility of thiamine deficiency due to the long standing anorexia induced by abdominal congestion should be considered in every patient with congestive heart failure The suspicion should be particularly strong when treating elderly males who live alone or individuals who partake freely of alcohol In the younger group of patients with valvular disease the possibility that smoldering rheumatic myo carditis or bacterial endocarditis is present should be kept constantly in mind

It is perhaps even more important to look for evidences of those types of cardiac disease which are particularly amenable to surgical management Mitral stenosis may be readily overlooked in a middle aged or elderly patient with auricular fibril lation The presence of obvious congestive failure may keep the physician from a careful search for such congenital disorders as coarctation of the aorta and patent ductus with a systolic murmur only Constrictive pericarditis is especially likely to be missed unless careful precordial palpation and fluoroscopic examination are carried out on every patient with congestive heart failure

3 *Is there a hitherto unsuspected complication?* In patients who have been subjected to repeated mercurial diuretics plus a long standing low salt diet and more particularly if anorexia has been an important symptom one should be on constant watch for those electrolyte disturbances already discussed They are likely to manifest themselves by the relatively rapid onset of refractoriness to mercurial diuretics and by the simultaneous ap pearance of marked lassitude and apathy The rec ognition of hypochloremic alkalosis of potassium deficit of sodium depletion of the salt depletion syndrome or a combination of these disorders should be made according to the criteria described above In the absence of some serious primary disease of the kidney or of some obvious grave intercurrent disorder the presence of refractoriness to mercurial diuretics constitutes strong evidence for the presence of one of these electrolyte dis turbances

Advanced renal disease frequently is present in patients with congestive failure and especially in those who have either hypertension or bacterial endocarditis During the initial phase of manage ment the manifestations of congestive failure may overshadow those of the less obvious but often more serious renal disease The coexistence of nitrogen retention and of a urine of low specific gravity despite a small urine volume makes it highly probable that there is grave functional im pairment of the kidneys and that the management of the cardiac failure and more particularly of electrolyte disturbances will be relatively unsuccess ful

Pulmonary infarction discussed in Chap 236 is one of the commonest causes of intractable heart failure If this complication is recognized and vigorously treated either with anticoagulants or in suitable cases by venous ligation the heart may again respond to treatment after a period of days or weeks has elapsed In many instances the ex pected manifestations (pleural pain hemoptysis and changes in the x ray) will be absent and the sole clues to pulmonary infarction may be unex plained elevations of temperature leukocyte count or sedimentation rate plus aggravation of the cardiac status and at times an evanescent increase in the serum bilirubin values

4 *Is the intractable heart failure due to extreme myocardial impairment?* This suspicion should be entertained seriously only after the problem has been approached from the standpoint of the ques tions above Once one is satisfied that the therapy is entirely adequate that there is no complicating unrecognized etiologic factor and no serious com plication one is justified in entertaining the ques tion of myocardial disease so advanced that the heart failure has become and will remain intracta ble Under such conditions the patient has little to lose by receiving radioactive iodine and he may receive some benefit from it

227 HYPERTENSIVE VASCULAR DISEASE

John P Merrill

Arterial hypertension in man may be arbitrarily divided into two categories pulmonary hypertension and systemic hypertension (Table 115) The more important problems related to pulmonary hypertension have been considered in Chap 224

Systemic hypertension is the manifestation of an abnormal state of the circulation just as fever is a sign of altered temperature regulation The word *hypertension* in itself implies nothing as to the associated prognosis or organic vascular or renal disease Indeed the role of elevated blood pressure in the production of aggravation of vascular disease is a disputed but important association which will be discussed separately As a clinical phenomenon hypertension may be diagnosed if on repeated examinations the blood pressure is found to be above that considered normal for adolescents of similar racial and environmental background In North American adults 140/90 may be regarded as abnormally high arterial pressure for coolies in Peiping 125/80 might have a similar significance

It is now apparent that the hypertensive syndrome has no single clear cut etiology Many factors are involved some of which may be thought of as mere exaggerations of the physiologic mechanisms by which normal arterial pressure is maintained Others are obviously abnormal in the sense that they play little or no role in normal circulatory regulation and are prominent only in disease states Any or all of these factors may be involved in any given case of hypertension It is not surprising therefore that in spite of a vast amount of interest and work no single therapeutic agent for the treatment of hypertension has come to light The physician or student who undertakes to study or treat hypertension must seek to understand the various mechanisms which may be involved when he attempts to evaluate their importance in the individual problem

FACTORS DETERMINING BLOOD PRESSURE

Blood flow through the normal vascular bed may be thought of as a system in which pulsatile flow

One of the commonest causes of refractory heart failure is the presence of an electrolyte disturbance These disorders have been considered above

2 *Is there an unrecognized etiologic factor which might be successfully treated?* One thinks first of all of masked thyrotoxicosis This condition may present none of its usual clinical manifestations when occurring in an elderly patient with congestive heart failure One should entertain a high degree of suspicion toward such physical signs as unusual softness of the skin excessive sweating frequent bowel movements heat intolerance unexplained tachycardia etc Even with a high index of clinical suspicion patients with thyrotoxicosis will be overlooked unless one makes it a rule to determine the protein bound iodine of the serum in all patients with congestive failure

Chronic arterial hypoxia due to primary disorders of the lung is frequently complicated by congestive heart failure and may be strikingly benefited by oxygen therapy properly administered Anemia of clinically significant degree is usually obvious upon inspection of the patient s skin and mucous membranes but it may be overlooked The possibility of thiamine deficiency due to the long standing anorexia induced by abdominal congestion should be considered in every patient with congestive heart failure The suspicion should be particularly strong when treating elderly males who live alone or individuals who partake freely of alcohol In the younger group of patients with valvular disease the possibility that smoldering rheumatic myocarditis or bacterial endocarditis is present should be kept constantly in mind

It is perhaps even more important to look for evidences of those types of cardiac disease which are particularly amenable to surgical management Mitral stenosis may be readily overlooked in a middle aged or elderly patient with auricular fibrillation The presence of obvious congestive failure may keep the physician from a careful search for such congenital disorders as coarctation of the aorta and patent ductus with a systolic murmur only Constrictive pericarditis is especially likely to be missed unless careful precordial palpation and fluoroscopic examination are carried out on every patient with congestive heart failure

3 *Is there a hitherto unsuspected complication?* In patients who have been subjected to repeated mercurial diuretics plus a long standing low salt diet and more particularly if anorexia has been an important symptom one should be on constant watch for those electrolyte disturbances already discussed They are likely to manifest themselves by the relatively rapid onset of refractoriness to mercurial diuretics and by the simultaneous appearance of marked lassitude and apathy The recognition of hypochloremic alkalosis of potassium deficit of sodium depletion of the salt depletion syndrome or a combination of these disorders should be made according to the criteria described above In the absence of some serious primary disease of the kidney or of some obvious grave intercurrent disorder the presence of refractoriness *to mercurial diuretics constitutes strong evidence* for the presence of one of these electrolyte disturbances

Advanced renal disease frequently is present in patients with congestive failure and especially in those who have either hypertension or bacterial endocarditis During the initial phase of management the manifestations of congestive failure may overshadow those of the less obvious but often more serious renal disease The coexistence of nitrogen retention and of a urine of low specific gravity despite a small urine volume makes it highly probable that there is grave functional impairment of the kidneys and that the management of the cardiac failure and more particularly of electrolyte disturbances will be relatively unsuccessful

Pulmonary infarction discussed in Chap 206 is one of the commonest causes of intractable heart failure If this complication is recognized and vigorously treated either with anticoagulants or in suitable cases by venous ligation the heart may again respond to treatment after a period of days or weeks has elapsed In many instances the expected manifestations (pleural pain hemoptysis and changes in the x ray) will be absent and the sole clues to pulmonary infarction may be unexplained elevations of temperature leukocyte count or sedimentation rate plus aggravation of the cardiac status and at times an evanescent increase in the serum bilirubin values

4 *Is the intractable heart failure due to extreme myocardial impairment?* This suspicion should be entertained seriously only after the problem has been approached from the standpoint of the questions above Once one is satisfied that the therapy is entirely adequate that there is no complicating unrecognized etiologic factor and no serious complication one is justified in entertaining the question of myocardial disease so advanced that the heart failure has become and will remain intractable Under such conditions the patient has little to lose by receiving radioactive iodine and he may receive some benefit from it

particularly in the elderly arteriosclerotic patient Here failure of the rigid vessel wall to distend with the systolic thrust of the heart results in a sudden increase in pressure in the system producing a high systolic pressure Similarly lack of elastic "recoil results in a rapid drop of pressure in diastole and this failure to maintain the resting pressure in the vascular bed may be recorded as a low diastolic pressure

4 An increase in *cardiac output* such as is mediated through exercise fever or thyrotoxicosis may cause increases in blood pressure by increasing the amount of blood pumped into the vascular system per unit of time Since the effect is primarily a result of the ventricular contraction the predominant effect upon blood pressure is an increase of the systolic phase As a clinical phenomenon this has much less significance for the hypertensive syndrome than does elevation of the diastolic blood pressure Decrease in cardiac output secondary to severe myocardial damage results in hypotension If compensatory vasoconstriction occurs the diastolic pressure may be relatively well maintained and the hypotension is characterized by a low systolic and a narrow pulse pressure

5 The single most important factor in the production of the type of arterial hypertension with which the physician is usually concerned is an *increase in peripheral resistance* The greatest part of this increase is contributed by the arteriolar segments Relatively small changes in caliber cause marked changes in resistance which varies inversely as the fourth power of the radius of the lumen Thus a decrease of 10 per cent in the average arteriolar lumen will lead to a rise of 30 per cent in mean arteriolar resistance The diastolic pressure which represents the residual resistance in the peripheral vascular bed after systole more closely reflects the factor of peripheral resistance As reflecting this factor elevation of the diastolic pressure is of crucial importance in the syndrome concerned in a study of hypertension in man though systolic hypertension alone which may result from several causes of increased stroke volume may have little bearing in itself *Decrease* in arteriolar tone secondary to toxins nervous influence or drugs results in increase in caliber and may produce *hypotension*

Alterations in blood pressure in either direction produced by changes in any of the five factors previously mentioned are modified by reflex arcs of the autonomic nervous system Through vasoconstrictor or vasodilator fibers these arcs change arteriolar tone and lumen following appropriate stimulation of receptors on the afferent side of the arc Similar reflex arcs modify the cardiac output Medullary centers exist for control of cardiac rate as well as for vasoconstrictor and vasodilator effects These medullary centers in turn may be influenced by higher vasomotor centers situated in the hypothalamus and possibly even in the cerebral cortex Stimulation of vagal afferent fibers located in the aortic arch and the heart may result in alteration in caliber of the blood vessels through impulses transmitted via these vasomotor centers over efferent fibers to the vasculature A rise in blood pressure by stretching special proprioceptors in the aortic wall is thought to be the stimulus for the resultant depressor response Similar receptors are located in the carotid sinus Stimulation of these by increase in pressure may lead to vasodilator responses whereas decrease in pressure may produce a vasoconstrictor reflex through the afferent limb of the reflex arc The sinus and aortic nerves are the so called buffer nerves" and together make up an important mechanism for controlling arterial blood pressure The rise in diastolic pressure which occurs when the upright position is assumed is one of the many important manifestations of this control

INCREASES IN BLOOD PRESSURE SECONDARY TO CHANGES IN ARTERIOLAR CALIBER

From the foregoing it would appear that factors which influence arteriolar tone and caliber play an important role both in maintaining normal blood pressure and in producing hypertension The following factors have been thought to be of importance in influencing arteriolar tone

Decrease in Vasodilator Tone Some authorities hold that the kidney elaborates a vasodilator substance whose production is impaired in renal disease or nephrectomy Practical applications of this theory are lacking in the clinical hypertensive syndrome

Humoral Agents Which Raise Smooth Muscle Tone For more than half a century workers in the field of hypertension have been interested in circulating humoral substances whose primary action is to increase arterial tone Some of these substances have been thought to arise in the central nervous system but the greatest interest has centered around the release by a kidney whose blood supply has been compromised (though not made anoxic) of a substance (renin) which by interaction with a serum globulin is capable of causing an increase in smooth muscle tone in arterioles The resultant pressor substances (angiotonin hypertensin) have been investigated and in some cases antiserums to renin have been prepared which will prevent its action in animals Among the many other substances found in the circulating plasma of hypertensive animals causing pressor responses are serotonin and pherentasin Investigators have isolated from dogs a pressor substance released from the central nervous system on centripetal vagal stimulation

Table 115 CLASSIFICATION OF HYPERTENSION

I Pulmonary hypertension
II Systemic hypertension
- A Systolic hypertension only
  - 1 Increased stroke volume
    - *a* Thyrotoxicosis
    - *b* Anemia
    - *c* Heart block
    - *d* Arteriovenous fistula
    - *e* Psychogenic
  - 2 Rigidity of the aorta
    - *a* Arteriosclerosis
- *B* Combined systolic and diastolic hypertension *
  - 1 Renal
    - *a* Pyelonephritis
    - *b* Glomerulonephritis
    - *c* Congenital lesions
    - *d* Obstructive lesions
    - *e* Renal vascular occlusion
  - 2 Endocrine
    - *a* Acromegaly
    - *b* Adrenal cortical hyperfunction
    - *c* Pheochromocytoma
  - 3 Neurogenic
    - *a* Brain tumor (rapidly expanding)
    - *b* Cerebrovascular accidents
    - *c* Diencephalic syndrome
    - *d* Poliomyelitis
    - *e* Psychogenic
  - 4 Unknown etiology
    - *a* Essential hypertension (benign)
    - *b* Eclampsia
  - 5 Miscellaneous
    - *a* Coarctation of the aorta
    - *b* Increased intravascular volume

* Any of the conditions associated with diastolic hypertension may become rapidly progressive (malignant) This occurs much more frequently in the so called essential hypertension

occurs in a series of elastic tubes The larger tubes represented by the arteries gradually decrease in caliber through the arterioles to the capillaries and similarly decrease the magnitude of each pulsation until in the capillaries the flow becomes steady In this system the pulsating force is provided by the contraction of the left ventricle the elasticity by the walls of the arteries and the major portion of the resistance to flow by the arteriolar bed The pressure produced at the peak of ventricular contraction in this elastic system is represented by the systolic blood pressure and the total resting resistance of the system in ventricular diastole by the diastolic pressure The difference between these two values is the pulse pressure The mean arterial pressure is usually thought of as one half the sum of the systolic and diastolic pressures However the true mean pressure which is the average pressure throughout the cardiac cycle is not faithfully reflected by this value since the fall in pressure from the systolic to the diastolic level is not a decline over a steady slope In measuring the arterial blood pressure the observer is assessing a value which is determined by a number of factors not ordinarily measured directly

We may consider these factors in order

1 Since increasing resistance to flow is developed by increasing viscosity *blood viscosity* is one factor altering blood pressure Blood viscosity is influenced chiefly by the concentration of the plasma proteins and of the white and red corpuscles suspended in it Marked polycythemia may thus give rise to hypertension both by reason of increased blood viscosity and by the increased whole blood volume

2 *The amount of whole blood or plasma in the intravascular compartment* contributes also to the arterial pressure Since the intravascular fluid except for the blood proteins is continuous across the capillary walls with extracellular fluid in general the volume of this latter compartment also contributes to arterial blood pressure Thus severe depletion of either or both compartments by bleeding or acute dehydration will produce hypotension increase of the volume of either may result in hypertension Factors modifying the retention or excretion of sodium and water will affect the volume of extracellular fluid and may produce alteration in blood pressure Since several factors of the adrenal cortex are concerned with sodium retention it is to be expected that hyperfunction of the adrenal cortex may be associated with excess salt and water retention increased plasma volume and hypertension Certainly many cases of adrenal cortical hyperfunction (Cushing s syndrome) exhibit hypertension whereas untreated hypoadrenalism (Addison s disease) may be characterized by hypotension This relationship is not a consistent one however for some patients with adrenal cortical hyperfunction show no hypertension and similarly patients with cyanosis and congenital heart disease who have increased blood volumes may fail to show hypertension Possibly in the latter instance a decrease in cardiac output may account for this as it certainly does in patients who with the development of heart failure show an increase in blood volume but a fall in cardiac output Thus modification of one of the five factors by another or all of the others may influence the alteration in blood pressure

3 In a sense *the rebound of the elastic arterial walls in ventricular diastole* serves to maintain the propelling force of the blood in the interval between systolic contractions It thus serves together with the peripheral resistance to flow in the arteriolar bed to maintain the resting or diastolic pressure in the vascular system The effect of decreasing elasticity of the large vessel walls may be seen

likely to be correlated with longevity In more than a third of the population however arterial hypertension as manifested by resting blood pressures of 150/90 or above may be noted as a transient phenomenon in early adult life and is the usual finding beyond the age of sixty Although in themselves such increases in blood pressure may be of little significance in any one individual statistics based on hundreds of thousands can leave no doubt that even occasional rises in resting levels of pulse and blood pressure are associated with a shortening of the life span

Factors of importance in alterations of arterial blood pressure may also be found in a consideration of race environment individual heritage and the state of activity Thus hypertension occurs earlier and in a higher percentage of Negroes both in the United States and in tropical Panama than in white or Indian populations Women develop hypertension slightly more frequently than men but appear to tolerate it better The basal pressures determined on awakening before morning activity begins are lower than during the day 90/60 in many healthy whites and 80/50 or less in many natives of the tropics and of Asia Sitting or standing normally raises the diastolic levels 5 to 10 mm Hg exercise and hypoxia or marked anemia lower the diastolic and raise the systolic level

Recent statistical studies indicate that although blood pressure tends to rise with age in the relatives of both hypertensives and nonhypertensives blood pressure elevations are found earlier in the relatives of the hypertensive population and tend to remain higher throughout their life span Similarly hypertension frequently develops earlier and with greater severity in successive generations with hypertensive predecessors In those with the hypertensive predisposition inherited or not a rise in systolic and diastolic pressures may be caused by chilling anger frustration anxiety or even pleasant anticipation of an exciting event whereas others with no predisposition may show no rise even with the most intense emotional stimuli The value obtained with the sphygmomanometer is thus only one of the many factors whose importance must be assessed in considering the significance of alterations in blood pressure

CLASSIFICATION OF HYPERTENSION

A system of classification of hypertension is presented in Table 116 It should be noted that systemic hypertension may be differentiated by reason of the phase in which the elevation occurs Marked elevation of systolic pressure with little or no elevation of diastolic pressure has a different etiologic connotation and even more important an entirely different prognostic significance than does elevation of the diastolic phase As has been pointed out previously predominance of systolic elevation depends more upon the factor of cardiac output Predominance of diastolic elevation is a manifestation of increased residual resistance in the peripheral vascular bed after systole and as such more closely represents the clinically significant abnormality in the hypertensive syndrome The term *essential hypertension* has been employed to indicate those cases of hypertension for which a specific endocrine or renal basis cannot be found and in which the neural element may be only a mediator of other influences Since even this latter relationship is not entirely clear it is more properly listed for the moment in the category of unknown etiology The term *essential hypertension* defines simply by failing to define hence it is of limited use except as an expression of our inability to understand adequately the forces at work Nevertheless the bulk of patients with significant and persistent elevation of diastolic pressure form a fairly uniform group for which no well defined etiologic process has been delineated From the standpoint of wide acceptance the term probably should be retained Unquestionably cases of essential hypertension in the progressive form may develop a renal component which perpetuates this syndrome as a result of development of vascular lesions in the kidney The development of vascular lesions here and elsewhere has served for some authors to differentiate *hypertensive disease* from *hypertension* which latter term connotes only elevation of blood pressure without associated vascular lesions The prognostic significance of this division is obvious but the dividing line is often difficult to draw Essential hypertension may be further subdivided into two types *benign* and *malignant* These terms should be employed only as relating to the rapidity and severity of the vascular disease accompanying increased blood pressure levels The malignant type may be superimposed upon the benign type occasionally however it may be so rapid in onset and so severe in its course as to appear a separate entity In addition the severity and rapid progress of vascular disease associated with hypertension primarily renal in

Table 116 CURABLE HYPERTENSION

Systolic hypertension only	*Combined systolic and diastolic hypertension*
Thyrotoxicosis	Brain tumor
Arteriovenous fistula	Unilateral renal disease
Anemia	Adrenal cortical hyperfunction
	Pheochromocytoma
	Pituitary tumors
	Coarctation of the aorta
	Increased intravascular volume
	Eclampsia
	Polycythemia

which has common properties with serotonin and has been postulated as an explanation for the failure of so called neurogenic hypertension to respond to sympathectomy To the great misfortune of the hypertensive population the role of all these substances in chronic hypertension in man is still obscure The hormones of the adrenal medulla however are humoral agents which can and do play a well defined role in some instances of human hypertension Primarily implicated are epinephrine and its demethylated analogue norepinephrine From the physiologic viewpoint norepinephrine appears more closely associated with the human hypertensive syndrome Its action is characterized by an increase in peripheral resistance (primarily because of increased small vessel tone) with no increase or an actual fall in cardiac output Functioning tumors of the adrenal medulla and chromaffin tissue elsewhere can closely mimic the clinical picture of hypertensive disease although in essential hypertension blood levels of norepinephrine are not elevated

Humoral Agents Which Potentiate either Neurotonic or Humoral Tonic Effects It has been suggested that the kidney may be the site of a vaso exciter material (VEM) which potentiates (in the experimental animal) the response of small arterioles to topical application of epinephrine Of much greater significance however is recent evidence both in the experimental animal and in human beings that the kidney s role in renal hypertension may be its failure to excrete or to metabolize a circulating pressor substance similar to or identical with norepinephrine With the exception of Cushing s syndrome the role of the adrenal cortical steroids in producing the usual varieties of hypertensive disease is still obscure We can only conclude from the wealth of experimental and clinical data that the adrenal cortex probably plays a role in the maintenance of hypertension much as it does in normotension

Nervous Constrictor Influence As an explanation for the increased peripheral resistance which appears to be common to the hypertensive syndrome almost independent of its etiology it is natural to inquire into the role of increased vasomotor tone Increased vasomotor tone and augmented spontaneous vasomotor activity have been observed experimentally under the microscope and are well known to occur in many hypertensive and prehypertensive patients Many factors which block or reduce sympathetic tone at high levels such as psychotherapy and sedation and sympathectomy and sympatholytic drugs at a more peripheral mechanism tend to decrease blood pressure Similarly factors known to augment constrictor nervous influence such as emotion and chilling tend to increase blood pressure Possibly in some cases the central nervous system participates by elaboration of the humoral agent It should be remembered also that the adrenal medulla is under the influence of nervous stimulation When the autonomic pathways are interrupted by chemical blockade of the sympathetic ganglions it has been found that in both normo and hypertensive patients blood pressure falls are greater when the initial blood pressure is high In both normo and hypertensive patients however elevation of the blood pressure by the administration of norepinephrine leads to a decrease in the extent of the blood pressure fall which may be obtained by ganglionic blockade In spite of the fact that vasomotor activity is not always increased in essential hypertension it is reasonable to conclude that neurogenic mechanisms play prominent contributory roles In established hypertension the vasomotor centers continue to regulate blood pressure levels in response to both pressor and depressor stimuli Thus although fixed hypertension is rare nervous influences however play a lesser role in well established or malignant hypertension because of the increased participation of humoral factors or because of decreased reactivity of the blood vessels secondary to pathologic change

CONSTITUTIONAL FACTORS IN HYPERTENSION

In attempting to assay the significance of alterations in blood pressure in the light of the various factors which have been delineated it is most important to remember that range of blood pressure compatible with normal activity and good prognosis may be extremely wide when compared with the range of such parameters as body temperature This is truer perhaps of the systolic than of the diastolic variation but it is to be emphasized that daily or even hourly fluctuations in blood pressure per se may be without real prognostic significance

In infancy arterial pressure may be 70/45 It then rises in late infancy and early childhood to values approximating 80/55 and by adolescence reaches levels of 95 to 110 systolic and 65 to 80 diastolic The upper limit arbitrarily chosen by many for the normal blood pressure in the adult is 140/90 All values cited above are approximations and fluctuations in either direction may occur without true prognostic significance Lower values are often diagnosed and treated as low blood pressure because of the well perpetuated myth that normal systolic blood pressure should equal the sum of 100 plus chronologic age Levels based on this formula however should be regarded as a statistically common misfortune rather than the ideal concomitant of advancing years In the absence of obvious causes for true hypotension values below that proposed by such a formula are in fact

mation of the hematocrit and erythrocyte count Phlebotomy the administration of phenylhydrazine hydrochloride radioactive phosphorus and irradiation have been used successfully in treatment *Pituitary tumors* accompanied by hypertension may be associated with the picture of hyperadrenalism or with that of acromegaly in which case the characteristic facies increase in head hand and foot size as well as x rays of the extremities and sella turcica may confirm the diagnosis The therapy of choice is irradiation

TOXEMIAS OF PREGNANCY

The toxemias of pregnancy are arbitrarily divided into preeclampsia and eclampsia Eclampsia is characterized by a more severe course and more diffuse lesions it differs from preeclampsia by the presence of convulsions and coma The syndrome is manifested by hypertension proteinuria and retention of fluid Common symptoms are headache visual disturbances and epigastric pain In the past the incidence of eclampsia has varied from 0 2 to 1 5 per cent With better prenatal care however this incidence has markedly decreased in recent years The disease is more common in primiparae than in multiparae though this may reflect only the decreased tendency of toxemic primiparae to become pregnant again Diabetes multiple births and hydatidiform moles are all reported as increasing the incidence of toxemias The primary pathologic lesions are seen in the kidneys and consist of thickening of the walls of the glomerular capillaries and the capillary basement membrane In the more severe cases petechial hemorrhages and small areas of necrosis are found in the brain In severe eclampsia the liver shows characteristic lesions consisting of irregular areas of hemorrhage and necrosis This may occasionally be severe enough to produce jaundice Bilateral symmetric necrosis of the cortices of the kidney occurs most often at the onset of eclampsia The etiology is still obscure Many of the reported cases of eclampsia may be simply the aggravation by the pregnant state of preexisting essential hypertension or of glomerular nephritis When these can be shown to be absent in the first 5 months of pregnancy it is postulated that a toxic or pressor substance formed in the placenta possibly at the site of placental infarction may be implicated in the production of the profuse vascular lesions

Course True eclampsia or preeclampsia rarely manifests itself before the sixth month of pregnancy In the cases which are carefully followed the earliest clues may be headache anorexia proteinuria elevations of blood pressure and excessive gain in weight There is frequently some degree of oliguria in eclampsia and in severe cases frank renal failure with anuria may supervene Marked hematuria is not usually seen except in association with cortical necrosis In the absence of frank renal failure renal blood flow is usually normal but there is characteristically a depressed filtration rate In the severe cases convulsions are characteristic and may be the cause of death Termination of pregnancy is usually accompanied by marked improvement although symptoms may continue for as long as 24 to 36 hr after delivery The recovery stage is usually characterized by a drop in blood pressure and a profuse diuresis with loss of edema The prognosis is good in carefully managed patients without severe renal lesions The internist must concern himself with the possibility of the development of permanent renal disease or hypertension following eclampsia Unfortunately there is no agreement on the frequency with which this occurs In most of the reported series some renal disease and hypertension persist following eclampsia but it is not clear whether this is due to aggravation of preexisting renal disease and hypertension or whether it dates specifically from the eclampsia Severe previous eclampsia in women over thirty five contraindicates a further pregnancy In the presence of slight hypertension or minimal urinary findings the patient may be allowed to become pregnant and carefully followed during her pregnancy with the possibility of electively terminating it when signs of eclampsia appear There is no good evidence that normal well-conducted pregnancy aggravates mild "essential" hypertension if toxemia does not supervene Patients with preexisting renal disease however may do poorly particularly if functional impairment exists

The *treatment of toxemia* should be divided into prophylactic and therapeutic measures Prophylaxis consists of careful surveillance with restriction of sodium to less than 2 Gm per day if edema appears The treatment of severe eclampsia is the termination of pregnancy Medical measures are similar to those outlined for the treatment of hypertensive encephalopathy Magnesium sulfate as well as protoveratrine has been used with good results It has been reported that the use of Apresoline in the hypertensive disease of toxemia of pregnancy is more specific than for other forms of hypertension Massive doses of penicillin which appear to exert some antitoxic action have been used with some success and good results have been reported from the prophylactic use of stilbestrol

SYSTEMIC HYPERTENSION

Signs and Symptoms The signs and symptoms of hypertension can rarely be attributed to the elevated blood pressure itself A large number of patients with elevated blood pressure may have

origin may justify the term *malignant hypertension*

Many factors involved in the hypertensive syndrome have now been delineated It may be permissible to attempt to integrate them in a theoretic case of human essential hypertension in a fashion which lays much stress upon the primary role of nervous vasoconstrictor influences In this idealized view an individual by reason of inherited traits including race and sex may be particularly susceptible to vasomotor reactions resulting from a stressful environment Specific reasons for this susceptibility might include emotional instability a labile vasomotor apparatus possibly including the vasomotor center in the medulla and a peripheral vasculature which hyperreacts to nervous constrictor stimuli Such an individual would manifest early in life greater rises in blood pressure in response to environmental stimuli than his fellow born without these genetic traits Such abnormal responses might be elicited by the cold pressor test and Valsalva maneuver During early adult life these rises would be more frequent reach higher levels and tend less and less to return to so called normal values The continued stress of pressure upon a genetically sensitive vasculature might then result in small blood vessel changes which would be manifest in the optic fundi and kidneys With the involvement of the kidneys and possibly the adrenals a second humoral mechanism might originate which could then overlay and finally completely dominate the original neurogenic origin At this point although the labile vasomotor response might still be elicited its importance from an etiologic and therapeutic standpoint would be secondary Such a formulation is admittedly speculative It does however fit many of the observed facts Although many doubt that increased pressure per se may cause vascular disease in the author s view the statistical correlation in mortality tables is too impressive to neglect By analogy too the pulmonary vascular disease that may result from prolonged increased pulmonary arterial pressure with mitral stenosis suggests very strongly that this relationship may obtain

A second and possibly more important classification has been constructed in Table 116 Such a table emphasizes the fact that the physician confronted with the problem of hypertension must think first of those situations in which the hypertension may be associated with a specific defect which may be amenable to specific therapy A causal relationship of this type may be difficult to establish and may be defined only by the resultant success or failure of therapy Nevertheless the opportunity to cure hypertension must be sought diligently in each hypertensive patient The diagnosis and treatment of *thyrotoxicosis* have been discussed in Chap 64 The presence of an *arteriovenous fistula* may be manifested by systolic hypertension and a wide pulse pressure and may be diagnosed by the presence of a murmur or thrill over the site of the abnormal communication This may be over the peripheral vessels where involved or a typical machinery murmur may be heard over the left precordium in the case of patent ductus arteriosus Both of these conditions may be amenable to surgical correction *Adrenal cortical hyperfunction* may be manifest by hypertension as well as the other signs of Cushing s syndrome (Chap 66) Osteoporosis hirsutism buffalo hump " striae and disorders of glucose metabolism are typical *Pheochromocytoma* though rare produces a completely curable form of hypertension when surgery is performed before the vascular disease has become irreversible In spite of such diagnostic techniques as perirenal air injection and retroperitoneal insufflations with oxygen the newer pharmacologic agents for provocative and blocking tests and the assay of urinary pressor amines the diagnosis remains extremely difficult and may be established only by exploration Pheochromocytoma in addition to the typical intermittent attacks may produce a steady hypertension The problem is discussed further in Chap 67 The diagnosis of *coarctation of the aorta* if considered will usually be made by comparison of blood pressure in the arm and leg and appropriate x rays of the chest may show the typical notching of the ribs *Unilateral renal disease* remains a problem Even when unilateral renal disease can be demonstrated in conjunction with hypertension involvement of the other kidney by vascular damage may militate against cure by nephrectomy Similarly a strong family background of hypertension may make the coexistence coincident rather than causal Occlusion of a renal artery or one of its branches should be suspected when malignant hypertension appears suddenly in patients with no previous history In suitable cases cures may be effected by nephrectomy or by the placing of arterial grafts Translumbar aortography may be the sole way to make this diagnosis since little impairment in over all renal function may be evident Where unilateral renal disease is suspected as a cause for hypertension careful functional studies of both kidneys should be made If such studies reveal no trace of disease in one kidney and marked involvement in the other removal of the diseased organ may be expected to produce significantly prolonged lowering of the blood pressure in about 50 per cent of the operated patients In the author s view the stress should be placed upon the presence of one completely normal kidney rather than total lack of function in the other since by the time this latter condition is evident both kidneys may well be involved *Polycythemia* as a cause of increased intravascular volume may be diagnosed upon esti

racial origins known to be susceptible to hypertensive disease with high relatively fixed diastolic pressures are apt to do badly On the other hand women apparently tolerate elevated blood pressure and even hypertensive vascular diseases better than do men Every physician interested in hypertensive disease has followed women and an occasional man through many years of relatively good health with persistent diastolic pressures of 120 mm or more The degree of retinopathy may give some clue as to the prognosis although this in general is a better guide to the progress than to the ultimate prognosis since even severe retinopathy may be reversed occasionally by appropriate therapy and rarely improves spontaneously Papilledema and renal insufficiency are extremely grave prognostic signs in every instance The occurrence in the hypertensive patient of myocardial infarction congestive heart failure or cerebral vascular accident signifies a poor prognosis although again every hypertensive clinic has its share of patients constituting exceptions to this general rule Emotional instability while making the treatment somewhat more difficult does not otherwise affect prognosis itself Poor response to adequate treatment of any sort including failure to correct obesity frequently indicates impaired prognosis

Diagnosis The diagnosis of hypertension may be made with a blood pressure cuff and the diagnosis of hypertensive vascular disease by the usual methods for evaluating the cardiovascular system kidneys and optic fundi The differential diagnosis should from the very first include disease states giving rise to hypertension for which more specific therapy exists A list of these which should be considered during the first evaluation of any hypertensive problem is given in Table 116

Table 117 FACTORS INDICATING AN ADVERSE PROGNOSIS IN HYPERTENSION

- Negro origin
- Youth and male sex
- Persistent diastolic pressure > 110
- Marked cardiac enlargement
- EKG changes of ischemia or left ventricular strain
- Renal functional impairment
- Retinal hemorrhages and exudates
- Angina pectoris
- Myocardial infarction
- Cerebrovascular accident
- Congestive heart failure
- Marked retinal arteriolar sclerosis
- Nitrogen retention *
- Papilledema

* Nitrogen retention when due to vascular disease of the kidney indicates a very grave prognosis Its occurrence in primary renal disease with only mild hypertension may be less important

Treatment

Principles of Therapy Whatever the form of therapy selected it must not be forgotten that the physician who treats hypertension is treating the patient as a whole rather than the separate manifestations of a disease The first principle of the therapy of hypertension is the knowledge of when to treat and when not to treat Two essentially opposing viewpoints are maintained in this regard with various shades of opinion in between Both agree that the accelerated phase of hypertension with a high diastolic pressure and rapid progress of vascular lesions in the retinas heart and kidneys markedly affects the prognosis and justifies any form of treatment aimed at lowering the blood pressure except in the presence of marked nitrogen retention The differences are sketched in Table 118

The viewpoint indicated on the right in Table 118 is espoused by the author and henceforth the discussion of therapy will be oriented from this point of view

Selection of Patients for Therapy In the decision to institute treatment the factors delineated in the paragraph on prognosis must bear considerable weight Factors of increasing gravity shown in Table 117 are increasingly important indications for specific therapy Frank nitrogen retention however may contraindicate and obviate any specific form of depressor therapy Sudden marked and persistent elevation of diastolic pressure may precede signs and symptoms and as such indicate need for therapy A knowledge of when to withhold specific treatment is equally important A woman who has tolerated her diastolic pressure of 120 for 10 years without symptoms or deterioration does not need immediate specific treatment for hypertension Marked elevation of systolic pressure with little or no rise in diastolic does not constitute an indication for depressor therapy This is particularly true in the elderly or arteriosclerotic patient even though the diastolic pressure may also be moderately elevated A trial of mild forms of therapy including psychotherapy reducing diets sedation or mild depressor agents which fails to improve signs or symptoms may justify more intensive forms of therapy The physician must however carefully weigh the value of making his patient blood pressure conscious by a specific regimen and regular follow up against real need for any particular form of therapy Above all in treatment or prognostication he must avoid engendering in the patient a fear of the disease which may be unwarranted in our present state of knowledge Promising therapies are available however and it should be remembered that the forms of treatment are not mutually exclusive Particularly it should

no symptoms or signs whatever In the more advanced stages of hypertensive disease signs and symptoms depend upon the organ involved by the vascular disease accompanying the hypertensive process These include of course cerebral arterial and arteriolar disease coronary artery disease congestive heart failure and renal failure which will be discussed in separate chapters A not infrequent early symptom is the presence of headache This may take any form but classically is a dull pounding occipital headache which is present upon awakening in the morning and tends to wear off during the day Many patients with hypertension complain of nonspecific difficulties such as weakness nervousness flatulence palpitation and dizziness Since hypertensive patients are prone to emotional and psychic difficulties it is frequently difficult to evaluate these symptoms

Epistaxis may occur as well as microscopic and even gross intermittent hematuria accompanied by moderate proteinuria The latter findings may signify vascular involvement of the kidney but should alert the physician to the possibility of preexisting renal disease An important physical finding which may give some clue to the prognosis and progress of the vascular disease is the change in the optic fundi Early changes may include diminution in caliber of the smaller vessels most distant from the disk Tortuosity of the larger vessels close to the disk occurs in hypertensive disease but may also be seen in arteriosclerosis without hypertension and is of little significance to the hypertensive process itself Nicking of the veins by the arterioles with marked variation in the arteriolar caliber is a pathognomonic sign An increased light reflex signifies thickening of the vessel wall With advancing changes small flame shaped hemorrhages and glistening white exudates may make their appearance A serious prognostic sign indicative of advanced disease is papilledema manifested by blurring of the disk margins This should be particularly evaluated at the temporal margin since some degree of blurring of the nasal margin may be physiologic Separation of the retina has been observed in the acute hypertensive episodes of eclampsia Although somewhat unusual there may be marked differences in the degree of involvement of the retinas The visual symptoms usually depend upon the degree of involvement and the location of the lesions

Patients with hypertensive disease occasionally suffer from acute episodes characterized by marked rise in blood pressure above the previous level and by disorders of the nervous system which last for minutes hours or days and then disappear without clinical evidence of lasting damage Such episodes described as *hypertensive encephalopathy* are not limited to any single etiologic type of hypertensive disease but are particularly common in association with renal disease especially where a common factor such as acute glomerulonephritis or disseminated lupus erythematosus has produced both vascular lesions and hypertension Spasm of cerebral vessels is generally thought to be the cause of these attacks although adequate demonstration of this has yet to be made Small thrombi and edema play a role in some cases This syndrome may frequently simulate the hypertensive crises of pheochromocytoma or mimic brain tumor The clinical syndrome appears in two forms depending upon whether the disturbances in the nervous system are chiefly of generalized or of focal nature

The general form usually appears in individuals without previous long standing hypertension It may occur in women with eclampsia and in children and young adults with acute glomerulonephritis Rapidly progressing malignant hypertension is frequently accompanied by hypertensive encephalopathy Aside from a rapidly rising blood pressure the attacks are characterized by headache visual disturbances which may progress to blindness papilledema vomiting stupor coma stertorous breathing psychoses and convulsions All of these manifestations may be hastened and enhanced by the administration of excessive amounts of fluid

The focal type of hypertensive encephalopathy may appear in any individual with chronic hypertension but is especially frequent in older individuals and in the malignant form of the disease Loss of consciousness convulsions and paralysis involving one half of the body are especially common and the clinical picture though reversible may exactly resemble cerebral vascular accident due to hemorrhage thrombosis or embolism at the beginning The differentiation may be impossible until the patient has been observed for a number of hours or even for several days

Prognosis in Hypertension Few problems in clinical medicine are as difficult or as controversial as the evaluation of the prognosis for any individual patient with early but marked hypertension Although the statistics of the insurance companies give us a clear picture of the trend individual variation in tolerance to hypertension and hypertensive disease is marked A few of the factors affecting prognosis have already been mentioned In Table 117 are listed factors which are known to affect adversely the prognosis in patients with hypertension These are listed in order of increasing gravity Systems of classification of hypertension characterizing the disease in varying grades of severity and with varying prognoses have been devised on the basis of (1) retinal changes and (2) a combination of the factors listed in Table 117 plus PSP excretion and response to sedation It can be concluded that young male patients of

an emotionally labile patient with numerous emotional problems and psychosomatic complaints cannot always be told—because of the absence of vascular or renal disease—simply to forget his problems In the vast majority of instances a discussion of the problem with reassurances fortified by mild medication and follow up visits at infrequent but regular intervals will do more good

Dietary Management Obesity is frequently a sign as well as a complication of the hypertensive personality Since it has an undoubted adverse effect upon prognosis and progress of the disease it should be specifically treated by an adequate weight reducing regime such as has been outlined in Chap 21 The patient should fully understand the necessity for this regime without being frightened by it

There can be no question but that in the hands of certain workers diets low in sodium and in protein have resulted in striking amelioration of hypertensive vascular disease Of these the so called rice diet " containing 200 mg of sodium 25 Gm of protein and approximately 2000 nonprotein calories is an example Recent work has indicated that it is the low sodium content rather than the protein deficiency that is responsible for the beneficial results The true rice diet probably does not maintain nitrogen balance and it must be strictly adhered to for at least 6 to 8 weeks during which time most patients find it extremely unpalatable More palatable diets may be planned which contain less than 600 mg of sodium chloride per 24 hr and among several excellent booklets on this subject one is prepared for the patient by the American Heart Association For the treatment of hypertension per se 0 5 Gm of sodium chloride constitutes a maximal dietary salt intake although congestive heart failure and edema per se may respond at slightly higher levels Cation exchange resins which prevent absorption of dietary sodium have been used with success to effect decreased sodium absorption from diets containing more than 1 Gm of ingested sodium chloride and mercurial diuretics are an additional adjunct Such programs may make meals more palatable for many patients particularly with the judicious use of one of the salt substitutes The usual precautions should be observed with the ingestion of cation exchange resins A low sodium intake may effectively potentiate the effect of other forms of treatment both surgical and pharmacologic

Drug Therapy The rationale for the use of drugs which lower blood pressure is based on the belief that prolonged marked elevation of systemic arterial pressure is in itself harmful and may contribute to and hasten the vascular lesions While this view is regarded with skepticism by some there can be no question but that there are well documented cases in which the use of depressor drugs has aborted or reversed progressive changes of malignant hypertension Furthermore there is evidence that patients with severe hypertension whose blood pressure has been effectively lowered by drug therapy over a period of 3 to 4 years may then be maintained on gradually decreasing doses and eventually no drug at all Since peripheral resistance is the most important of the factors which determine the level of the blood pressure hypotensive agents to be effective therapeutically should act by decreasing resistance rather than by decreasing cardiac output or flow The introduction of hypotensive agents with varying sites of action has provided the physician with a new approach to medical therapy of hypertension These drugs although effective require of the physician a thorough knowledge of the disease as well as of the agent employed In Table 119 are listed in some detail the important properties of five currently available hypotensive agents which the author believes to be worthy of trial when hypotensive therapy is indicated Others such as dehydrogenated ergot derivatives (dihydroergocornine) the nitrites and the crude veratrum viride derivatives (Veriloid) do not appear to be of similar value either because of lack of efficacy or because of the limited margin between the therapeutic and toxic effects The use of sodium thiocyanate and nitroprusside whose actions are similar has been found by some to be effective in the treatment of hypertensive headache and in lowering of arterial pressure Because of the necessity for controlling blood levels however their use is not widespread

Of the agents listed in Table 119 the ganglionic blocking agents are of extreme and unquestioned potency Their side effects however as well as the need for careful control by frequent blood pressure readings suggest that their use should be relegated to the severer forms of hypertensive vascular disease The uncertain absorption from the gastrointestinal tract of the first three blocking agents listed in the table constitutes an additional difficulty although this particular objection appears to be overcome by Inversine which is completely absorbed In the author s own experience protoveratrine particularly in combination with Apresoline and reserpine has produced gratifying results in moderate hypertensives In other hands particularly in severe hypertensives the combination of the newer ganglionic blocking agents and Apresoline with or without reserpine has produced effective remissions It should be stressed that the increase in renal blood flow which occurs with Apresoline is not entirely consistent and that it results in part from increased cardiac output in which the renal share of the cardiac output may be actually decreased The prolonged use of Apresoline

Table 118 OPPOSITE VIEWPOINTS ON THERAPY OF HYPERTENSION

The exact level of the blood pressure may have little clinical significance since it correlates poorly with the incidence of vascular disease and with mortality figures Treatment of hypertension per se is unjustified	The level of diastolic pressure may not correlate with vascular disease or mortality in the individual but in a large series it can be statistically shown to shorten the life span
Spontaneous remissions of hypertensive vascular disease tolerance of it and response to nonspecific therapy make results of specific hypotensive therapy difficult to evaluate	In spite of the variables irreversible fatal vascular disease may result from essential hypertension There is reason to believe that elevation of the diastolic pressure contributes to this and in the absence of knowledge of other factors and with the ability to lower blood pressure with specific therapy attempts to lower pressure seem justified in properly selected cases
The dangers and side effects of specific therapy may be worse than the natural course of the disease	Various effective forms of hypotensive therapy exist including psychotherapy It is justifiable to apply mild therapy to mild forms of hypertension and since the problems and dangers of therapeutic methods increase with increasing order of efficacy they may be justified in severe forms of the disease In experienced hands specific forms of therapy even though dangerous need not be delayed until irreversible changes have taken place

be remembered that the confidence patience and enthusiasm of the physician are important ingredients in any form of therapy The hypertensive process being what it is this factor undoubtedly accounts in large part for the varying degrees of success achieved by different investigators with the same therapeutic program

Symptomatic Therapy Improvement in symptoms as well as blood pressure levels frequently results from adequate psychotherapy (see below) For the relief of hypertensive headache elevation of the head of the bed during the night is usually beneficial Thiocyanate salts have been used with some success although the necessity for carefully checking blood levels of this drug to prevent toxicity has greatly decreased its usefulness Not infrequently a cup of black coffee or the administration of 200 to 400 mg of caffeine as the citrate or sodium benzoate salt given on arising may help the hypertensive headache Periodic venesection has met with occasional success in alleviating headache and dizzy spells Small amounts of sedation in properly selected patients may be of some value They should be carefully evaluated after preliminary therapeutic trial for the undesirable side effects With renal failure the short acting barbiturates Seconal and Amytal are preferable to phenobarbital since they do not require the renal route for their excretion Because sedation may play a more fundamental role in hypertension than that of symptomatic therapy its use becomes a highly individualized problem The administration of 30 mg of phenobarbital three to four times a day to one patient may well dull the knife edge of anxiety and result in improvement In other individuals the mental confusion that may result as well as the necessity for taking medication continually may do more harm than good The conscientious executive faced with a problem which he is capable of solving with a clear head does not benefit his hypertensive disease by grappling with his problem under the influence of sedatives which cloud his thinking Such situations must be carefully assessed on their individual merits The tranquilizing agents (Miltown Equanil) may be useful in allaying anxiety and tension without impairing critical faculties

Psychotherapy A majority of patients with essential hypertension have disorders of personality which may be aggravated by environmental or emotional stress resulting in conflicts and anxiety which may be correlated with fluctuations in blood pressure Although there is little agreement on the specific personality patterns involved such emotional contributions may be recognized frequently they are particularly evidenced in the tense anxious individual with marked fluctuations in blood pressure In such cases psychotherapy alone has produced results equal to the best of other forms of therapy It is moreover an indispensable adjunct to them Intensive psychotherapy may not be necessary and indeed should not be undertaken unless it can be followed to completion since the early part of the exhaustive psychiatric approach may often be followed by exacerbation of hypertension One should not underestimate the value of the psychotherapy resulting from a good physician patient relationship It is probable that just this resulted in the improvement in hypertension attributed to nostrums such as watermelon seed and garlic It follows from this example however that

may give rise to a syndrome resembling rheumatoid arthritis and disseminated lupus erythematosus This appears to be reversible with cessation of therapy and should not necessarily limit its usefulness

Dramatic and unquestioned therapeutic results have been obtained with the use of these substances They are toxic and dangerous in excessive dosage however and the margin between the toxic and the therapeutic dose is relatively narrow hence all such therapy should be begun in the hospital The hypotensive agents selected should be administered initially in less than effective dosage and increased slowly until either the desired therapeutic effect or toxicity supervenes As with insulin therapy it may be wise under controlled conditions in the hospital to familiarize the patient with mild toxic effects so that they can be recognized Alternate dosage with the initial agent and one of the others or preferably the potentiation of the depressor effect of the initial agent by the addition of small doses of another drug may increase the depressor effect while decreasing the side effects inherent in both Such a combination too may minimize the effect of tolerance to either agent Experience suggests that the concurrent use of two or three of these agents with different sites of action may be the method of choice When the patient s dosage has been established in the hospital he may be seen at less frequent intervals on the outside and the therapeutic effects may be increased without increasing toxic effects by the addition of a third agent or by the substitution of a new agent for one of the two when tolerance becomes apparent Potentiation of depressor effect can be achieved also by decreasing the sodium content in the diet Cessation of therapy should never be abrupt, since dangerous hypertensive rebounds may result The necessity for carefully controlling the use of these agents carries with it the disadvantage of making the patient drug conscious and blood pressure conscious Once he has become familiar with the drugs however and confident of their therapeutic benefits he may learn to regulate them by taking his own blood pressure in the same manner that an intelligent diabetic regulates his insulin by testing his urine

The presence of advanced renal failure contraindicates the use of the drugs listed here with the possible exception of small doses of Dibenzyline (10 to 20 mgm t i d) This appears to be useful in hypertension with renal failure possibly through its action on unexcreted pressor amines In mild renal failure large doses of reserpine (2 to 5 mgm per day) or the combined use of ganglion block and Apresoline may be of value In properly selected cases an initial increase in nitrogen retention may be followed later by improvement in renal function although at considerably decreased blood pressure levels

Surgical Therapy In the past interruption of the autonomic pathways by sympathectomy particularly by the lumbodorsal technique of Smithwick, has produced a convincing decrease in mortality in some severe cases of hypertensive vascular disease This treatment should probably be reserved until after drug and/or dietary treatment has been tried and failed or been rejected In this sense its value has the same relationship to medical therapy as does the surgical treatment of peptic ulcer Undesirable side effects of sympathectomy are postural hypotension and disturbance of sexual function in the male Renal failure cerebral vascular accidents and congestive heart failure are contraindications Bilateral total adrenalectomy as a treatment for hypertension is still in the process of evaluation but may be of value in intractable congestive heart failure with minimal renal functional impairment

Pyrogens It has been reported that a prolonged course of high fever induced by the intravenous administration of pyrogens may be effective in some cases of malignant hypertension This is drastic treatment for a drastic disease state and should be carried out only under the supervision of those with some degree of experience in this technique

Treatment of Hypertensive Encephalopathy The incidence and clinical picture of hypertensive encephalopathy has been described earlier in this chapter Although in certain cases hypervolemia may contribute greatly to the abnormality the common denominator is hypertension due largely to generalized vasospasm It is rational therefore to attempt to lower the diastolic blood pressure by pharmacologic means This may be done effectively in children and in a small percentage of young adults by the intramuscular injection of a 50 per cent solution of magnesium sulfate in doses of 0 2 ml per kg of body weight This may have to be repeated several times at 4 hr intervals to keep pressure at satisfactory levels following which the oral administration of from 13 to 30 ml of 50 per cent magnesium sulfate two to three times a day may satisfactorily control the blood pressure If intravenous injection is necessary a 3 per cent solution of hydrated magnesium sulfate may be given slowly One hundred and fifty mg of the salt per kg of body weight is given over a period of 1 hr The effects of overdosage *(somnolence respiratory difficulty)* may be counteracted by the administration of a 10 per cent solution of calcium gluconate by vein Oxygen therapy sedatives and occasionally venesection and spinal tap may be useful Dramatic results have been observed with the use of intravenous or intramuscular Protoveratrine or with large doses (2 to 5 mg of parenteral reserpine) and with the continuous drip of an

cially palmitic acid whereas in the plasma unsaturated esters predominate

In the last decade Groen Kinsell Ahrens and Bronte Stewart have shown that in man blood cholesterol levels rise whenever the ratio of saturated to unsaturated fats in the diet rises even with constant total fat and cholesterol content of the diet Cholesterol is constantly being synthesized in the tissues of all animals cholesterol is excreted and reabsorbed from the bile The normal person pours 1 5 Gm of cholesterol into the gut on a low fat diet and reabsorbs about 1 2 Gm On a diet rich in fat but cholesterol free bile flow is increased and reabsorption may exceed 2 Gm Since it takes six eggs to provide 2 Gm of cholesterol it is perhaps not surprising that cholesterol added in modest doses to human diets raises the blood level so little If esterified with unsaturated fat such as corn oil there may be no rise in blood level from such a regime although esterified with inert saturated fats such as palmitic or stearic from butter or synthesized from excess carbohydrate the cholesterol provided in the bile might permit the maintenance of elevated plasma levels

Actual experience in laboratory study of animals and field surveys of human populations shows that diet is the essential basis of atherosclerosis On a starvation level of protein and carbohydrate no one will get the disease on the high animal fat intake of the American Army coronary disease is ten times as frequent as in men under thirty five years old in armies living without milk cream butter or eggs

Atherosclerosis can occur whenever the diet is as rich in cholesterol and saturated fat as is whole milk but the rate on such a diet and the blood lipid composition will vary enormously with endocrine and other metabolic factors the site of deposition will also vary at any given level of blood lipid in different people

During the years of active sex gland function women form more gallstones than men and white men and colored women have more severe coronary atheroma than the opposite sex Aortic atheromatosis shows little sex difference in humans or in chicks But cockerels on cholesterol rich diets have more severe coronary disease than hens of the same age and this process can be retarded by estrogens which have no influence on aortic lesions

It is a curious fact that the regimes which raise blood cholesterol and cause lipid deposition in the intima also hasten blood clotting retard fibrinolysis and predispose to thromboembolic disease Since many clinical episodes due to vascular obstruction result from thrombosis on atheromatous plaques and some pathologists consider mural thrombus formation important in the genesis of atheroma it is worth noting that postoperative thrombosis and embolism decreased in parallel with coronary disease during wartime food rationing in Norway and that both rose sharply after realimentation " In Asiatic cities where coronary disease is rare thromboembolism also is uncommon A high fat meal especially one rich in saturated fatty acid shortens the clotting time for many hours and the diet which lowers alimentary hyperlipemia and blood cholesterol will also protect against intravascular clotting Thus diet is doubly important in causation and prevention of the commonest and most fatal form of vascular disease—coronary occlusion

Local factors obviously play a great role in atherosclerosis for we see young men dead of severe coronary disease with no visible lesion elsewhere and elderly women with ulcerated extensive aortic disease and only a few small coronary plaques Intimal thickening whether inborn as in the epicardial part of the coronary arterial bed or acquired as in syphilitic mesaortitis or in the small arteries of the shrunken pyelonephritic kidney predisposes to rapid local deposition of lipid when plasma lipid levels are abnormal Even at birth the coronary arteries of human beings and of other mammals have remarkable intimal struts or cushions as thick or thicker than the media and far thicker than the intima in any arteries of the same caliber elsewhere in the body These struts are more developed in males than females even at birth They vary greatly from individual to individual and undoubtedly explain the great predisposition of coronary vessels to atherosclerosis

HYPERTENSION AND ARTERIOSCLEROSIS

When animals are put on regimes which cause atherosclerosis lesions develop more rapidly in those made hypertensive by renal embarrassment or other experimental techniques People with pulmonic hypertension have relatively severe atherosclerosis in the arteries going to the lung whereas in most people with pulmonic pressures one fifth as high as systemic the arteries of the lung show few or no lesions even when the aorta and its branches are seriously impaired Yet hypertension alone with low plasma lipid levels causes no atherosclerosis in men or animals

It is especially in the small arteries of the kidney and the retina that we see severe lipid deposition in hypertensives with high blood lipids although normotensives with the same chemical defect show few or no lesions in small arteries Diabetics on insulin and the usual (high) American levels of fat and salt intake show far more severe precocious arteriolar and even capillary and venular lesions of the retina and of the kidney than do nondiabetics In the retina the arteriolar lesions

aqueous solution of Arfonad a rapidly acting short lived ganglionic blocking agent whose effect by this route can be easily controlled by the rate of the drip

228 ARTERIOSCLEROSIS

William Dock

The media of the arteries of men and animals show varying degrees of loss of muscular and elastic elements as age advances and with this the vessels become tortuous and dilated This change affecting temporal and splenic arteries and the aorta may be well advanced by the fourth decade of life A similar change in the walls of the veins predisposes them to varicosity and to formation of hemorrhoids But in the arteries neither this medial change nor medial calcification which is less frequent and occurs later in life leads to occlusion of the lumen or rupture of the wall The involutional changes in the media have few or no clinical sequelae

When age or involution of parenchymal or muscular organs leads to atrophy or in the brain to progressive loss of neurones the vascular bed atrophies and the intima proliferates A lumen adequate for the needs of the shrunken organ remains but intimal thickening free of lipid and physiologically harmless may lead the unwary pathologist to ascribe atrophy to arteriosclerosis This is most often said of the cerebrum in the uterus or ovaries atrophy is accepted as a normal concomitant of aging and not blamed on the obvious regenerative intimal thickening

All the changes mentioned above are seen in aged mammals they are usually bilaterally symmetrical and widely disseminated or diffuse This contrasts strikingly with the patchy atheromas lipid rich intimal thickenings which occur very rarely in aged wild or domestic animals or even in primitive or very poor populations but are apparent in the bodies of most prosperous people on the diets usual in North America and Western Europe by the age of forty As noted by Lober the process of lipid deposition in the intima of coronary arteries begins with suckling and in our culture continues throughout life In rabbits and in most human populations lipid deposition ends with weaning and the deposits are reabsorbed during growth During suckling blood cholesterol rises in man or rabbit from the natal level of 60 mg per cent to 180 mg per cent or higher and in rabbits reverts to the neonatal level on weaning In human populations living on grain vegetables fish and lean meat the levels run from 120 to 180 mg per cent rising over 200 after maturity

DIET AND ATHEROSCLEROSIS

In rabbits and chicks it is easy to raise blood cholesterol and start lipid deposition which progresses to atherosclerosis merely by adding cholesterol to purely vegetable diets In dogs rats and monkeys it is necessary either to destroy the thyroid or deplete the protein stores or to add large quantities of saturated fat to the usual diet before added cholesterol will sharply elevate blood cholesterol and cause gross atherosclerosis In these species high fat diet thyroid ablation or protein depletion alone will not cause the changes in plasma or intima—cholesterol must be fed in adequate quantities These animal experiments were initiated because it was obvious to clinicians and pathologists by the dawn of the twentieth century that neither cholesterol gallstones nor atheromatous vessels were encountered among poor or primitive people as often as among the rich or among vegetarians as often as among pastoral people who consumed milk in large quantities throughout life

Just as gout is associated with high plasma urate levels and with rich diets atherosclerosis is associated with high plasma cholesterol levels and diets rich in animal fat and cholesterol The lipid in the atheroma is cholesterol plus lecithin cephalin and sphingomyelin in about the same ratio as these are found in the beta globulin fraction of the plasma and with much less lecithin than in the alpha globulin fraction The cholesterol in the plaques is mostly esterified with saturated fatty acid espe

salt and calories is essential to prevent disease in many cases controlled by insulin

When arteriosclerosis removes people from active life after the period of maximum fertility has passed it benefits the young It relieves them of the care of parents or brings them an inheritance as they enter adult life But this biologic blessing must be paid for later for the way to avoid this disease is to have and to be responsible for long lived ancestors In an urban society this tends to favor late marriage and few or no children The high incidence of arteriosclerosis in the social group which has longest urban existence—the Jews—is to be correlated with their maintaining the dietary taste for dairy products and with the biologic advantage of losing parents who have passed the age of sixty Any attempts to eradicate such a disease from an urban population will be frustrated by natural selection and the survival of more grandchildren in families with few living grandparents Those best fitted to survive in a world growing more urban are those whose parents and in laws vanish and leave a nice nest egg as soon as possible after the children reach marriageable age Atherosclerosis and neoplasia are now the chief factors in determining that we do not overstay our allotted span of life too long

229 DISEASES OF THE AORTA

Ben Friedman

CONGENITAL ANOMALIES OF THE AORTA

Some congenital malformations of the aorta are entirely benign others are incompatible with life beyond the intrauterine stage Symptoms can be attributable to three fundamental defects

1 *Obstruction or limitation of the blood stream* due to atresia stenosis and coarctation These are discussed in Chap 225

2 *Admixture with unoxygenated blood* resulting in cyanosis and hypoxia This may arise from a persistent truncus arteriosus from aortic atresia with a patent ductus arteriosus and from partial or complete transposition of the aorta The tetralogy of Fallot and the Eisenmenger complex are the only conditions in this group likely to permit life to adult age (see Chap 225)

3 *Compression or displacement of mediastinal structures* by vascular rings" These anomalies of the aortic arch may occur as isolated defects or in combination with other malformations They derive from the embryonic aortic arch pattern which encircles the primitive foregut Complete and incomplete forms are observed with the descending aorta lying either to the right or to the left of the mid line In the complete type a functional double aortic arch encircles the esophagus and trachea Variation occur in which portions of the right or left arch atrophy resulting in unusual origin and position of the major branches Most of these malformations are symptomless Dysphagia (dysphagia lusoria) hoarseness or respiratory distress occasionally result from compression of the esophagus trachea or recurrent laryngeal nerve by an anomalous subclavian artery which courses behind the esophagus by undue tension of the ductus arteriosus and pulmonary trunks or by a double aortic arch The abnormal position of the aorta and the anterior displacement of the esophagus and trachea can be detected readily by means of the fluoroscope Symptoms can sometime be relieved surgically

can be seen evolving and we know that hypertension or diabetes may precede vascular disease for years and may regress when hypertension or diabetes is controlled. *Here there can be no question* as to which comes first

EFFECTS OF EXERCISE AND OF SMOKING

There is rather impressive statistical evidence that men doing work which imposes muscular exertion have a later and lower incidence of coronary disease than those *on the same sort of diet who* lead sedentary lives. There is similar evidence of lower and later incidence of coronary disease in men and especially in women who do not smoke as compared to pack a day smokers of the same sex. Even in short term experiments physical activity lowers blood cholesterol but there are no convincing studies proving that smoking raises the level. *It is obvious that the onset of clinical evidence of* coronary disease might be delayed by the collateral circulation which physical activity might favor or be hastened by vasoconstriction due to nicotine. There is striking evidence that smoking does upset the cardiac function of people with asymptomatic coronary disease and therefore might hasten clinical evidence of atherosclerosis affecting the heart. *Davis and his colleagues observed striking de*terioration in ballistocardiographic patterns of subjects with coronary disease when they smoked or absorbed nicotine. This occurred rarely in controls but in more than half of the coronary patients. It seems safe to regard lack of exercise and the use of tobacco as accelerating the onset of atherosclerotic disorders but there is no evidence that either can *of itself damage the arteries*

STUDY AND MANAGEMENT OF ARTERIOSCLEROTIC SUBJECTS

The presence of clinically significant arterial disease is disclosed only by seeing retinal lesions or detecting functional impairment of legs kidney heart viscera or brain which is associated with a clinical picture such as angina known to be due in most cases to arterial obstruction. Other vascu*lar disorders must be ruled out and some dis*turbance of plasma lipid demonstrated before progressive disease can be ascribed to atherosclerosis. *In the brain arteriosclerosis cannot be diagnosed* on the basis of impaired mentation personality change or the like. These may be due to involutional loss of neurones or to metabolic defects—pellagra myxedema lack of cobalamin being well recognized causes of what passes for cerebral arteriosclerosis. A focal lesion affecting sensation motion or some discrete cerebral area suggests atherosclerosis or embolism. In the case of the heart angina (in the absence of aortic valve lesion or paroxysmal hypertension) or myocardial infarction is associated with severe atherosclerosis in *nearly 90 per cent of patients. In the legs inter*mittent claudication and gangrene in more than half the cases are arteriosclerotic in origin

When the question of severity and extent of this disorder is raised careful history and examination suffice to indicate degree of damage done in various regions, and x rays may show calcific lesions in the aorta and the legs. But even meticulous study *will not detect any large proportion of the coronary* arteries which will become occluded in a few hours or years. It can however be predicted that those with bad family records of vascular accident those with high blood cholesterol and those with hypertension will in any given decade have far more vascular accidents than those without these signs. This fact is of importance to insurers but when *the doctor talks to a patient no good is done by* stressing bad prognosis unless it leads the patient to accept effective therapy or prophylaxis. The arteriosclerotic patient may live in comfort for years or survive a series of severe vascular accidents with unimpaired earning power and morale; he may become depressed and disabled by the thought of imminent death or invalidism if risk of *arterial disease is described to him*

Many patients with severe arteriosclerosis of the abdominal aorta or its large branches may be completely cured by surgical excision and replacement by graft or prosthesis. Others may have their disability moderated by drugs. The cholesterol level may be lowered markedly by sitosterol feeding at mealtime by use of chelating agents or by thyroid *extract triiodothyronine or triiodothyroacetate*. In men and in women past the menopause estrogen *therapy may lower the beta globulin cholesterol* fraction. But the physiologic *management would* appear to be weaning from dairy products and use of a diet based on lean meat skimmed milk fish and vegetable products

If cholesterol falls in 3 months continuation of the regime for life can be urged for those who would prefer long life to rich fare. Low salt diet can on the same grounds be recommended for *trial by the hypertensive person* and more drastic therapeutic endeavors when the threat to life or vision becomes more apparent. Lecithin inositol *choline potassium iodide vitamins and supervita*mins have failed to lower cholesterol levels. The value of sitosterol or of chelating agents such as versene *in lowering cholesterolemia in any given* case can be determined only if the diet and weight are kept constant while the agent is being tested. *In the hypothyroid person specific therapy post*pones vascular disease; in the diabetic patient the type of diet described above with restriction of

sionally to hypertension and uremia due to renal ischemia

Syphilis is the commonest known cause of chronic obstruction of the origins of the major arterial trunks in the aortic arch It is observed in association with diffuse or fusiform dilatation of the aorta more often than with saccular aneurysms The manifestations may vary ranging from symptomless anisosphygmia to complete obliteration of the subclavian and carotid pulses (*pulseless disease*) Syncopal seizures visual impairment and trophic alterations in the lens and iris may appear but collateral circulation is usually sufficient to prevent severe ischemic changes In rare instances prominent collateral arterial channels may develop over the chest similar to those observed in coarctation of the aorta except that the direction of flow is reversed (reversed coarctation) Diastolic murmurs of extracardiac origin may sometimes be heard over partially occluded vessels at the base of the heart Nonsyphilitic causes of the chronic obstructive aortic arch syndrome which have to be considered in differential diagnosis are healed dissection of the aorta trauma polyarteritis and arteritis of unknown cause (*Takayasu's disease*) which affects young females predominantly

Aneurysm may also result from arteriosclerosis cystic medial necrosis or congenital malformations With rare exceptions patients with syphilitic cardiovascular disease will have corroborative evidence of syphilis either by history or serologic tests in blood or spinal fluid or by physical signs apart from the cardiovascular system Treponemal immobilizing antibodies may be detected in the blood of subjects in whom reagin cannot be demonstrated by conventional tests Arteriosclerotic aneurysms are more likely to occur in the descending aorta and seldom erode bone Advanced syphilitic aortitis is frequently accompanied by extensive atherosclerosis which may be reflected radioscopically in disproportionate calcification in the ascending aorta Arteriosclerotic aneurysms of the abdominal aorta usually occur below the renal arteries syphilitic aneurysms occur generally at or above the renal arteries.

Widening of the aorta is best demonstrated by roentgenography For this reason examination of every syphilitic patient should include fluoroscopy and x ray of the aorta Expansile pulsation is sometimes dampened by intraluminal clots and periaortic inflammation thus presenting an appearance which simulates a nonvascular tumor Visualization of the aortic lumen by aortography can be of great help in differential diagnosis

Treatment of patients with cardiovascular syphilis concerns itself first with management of the complications such as congestive heart failure and angina pectoris It is probably wise to withhold treponemocidal agents until these complications are reasonably well controlled

It is generally agreed that antisyphilitic drugs administered in the early stages of syphilis will effectively prevent crippling cardiovascular manifestations later in life Once cardiovascular disease had become established there was no unanimity of opinion concerning the use of prolonged and potentially toxic chemotherapy However the effectiveness of penicillin in tertiary syphilis has influenced the decision in favor of specific treatment of all patients with cardiovascular syphilis (see Chap 153) Unfavorable reactions to penicillin treatment are uncommon in cardiovascular syphilis but can be particularly dangerous in patients with ostial stenosis When the presence of this type of lesion is suspected and particularly when angina pectoris cardiac enlargement or congestive failure occurs in the absence of aortic regurgitation or in disproportionate severity to a mild valvular insufficiency treatment should be initiated very cautiously employing preparatory bismuth subsalicylate in doses of 0 1 Gm weekly for a period of 4 to 8 weeks or starting penicillin treatment with minute doses which can be administered orally

Antisyphilitic treatment can be expected to kill spirochetes and relieve active inflammation It may relieve some of the symptoms and may retard progression of the disease but no amount of specific treatment will restore elastic tissue which has been lost An aneurysm once formed will persist and may progress because of local hemodynamic changes Attempts have been made to reinforce the wall of an aneurysm by wiring and electrocoagulation within the sac or by wrapping the outside with Polythene cellophane These procedures have had limited application and doubtful success At present the treatment of choice is surgical resection employing grafts where necessary

ARTERIOSCLEROSIS OF THE AORTA

Arteriosclerosis is the most common affection of the aorta The factors which are believed to contribute to its development are increased intravascular tension disturbances in circulating lipids affections of the nutrient vessels and the ill defined changes associated with aging (see Chap 46) The aorta usually becomes dilated elongated and tortuous Arteriosclerotic aneurysms are relatively uncommon and are more likely to affect the descending aorta Intimal changes range from microscopic deposition of lipid material to pronounced thickening and formation of large atheromatous nodules or plaques Secondary changes may develop in the form of necrosis small hematomas calcification and ulceration.

Arteriosclerosis of the aorta is generally symp

SYPHILIS OF THE AORTA

Treponema pallidum is unique among parasites in its predilection for the aorta. The incidence of aortic involvement in large groups of untreated syphilitics has been estimated to be between 70 and 95 per cent. The earliest lesions consist of perivascular inflammation and endarteritis of the vasa vasorum in the adventitia and media. Medial necrosis, fragmentation of elastic and muscle tissue, and scarring follow. The loss of elastic tissue results in dilatation varying from slight localized or diffuse widening to huge aneurysms. Occlusion of the lumen of large arterial branches may arise from a combination of inflammatory swelling, cicatrization, thrombosis, intimal thickening, and secondary atheromatosis. Gummatous aortic lesions are rare.

Clinically demonstrable syphilitic cardiovascular disease rarely occurs in individuals who have had syphilis for less than 10 years or in those who had even a moderate amount of antisyphilitic treatment in the early phase of the infection. Its incidence is highest in the fourth and fifth decades of life, in males, and in Negroes.

The manifestations are determined in part by the distribution of the lesions. *Angina pectoris* and *aortic insufficiency* arise as the result of involvement of the root of the aorta, at the site of the coronary ostiums and at the insertions of the valves. Both of these crippling lesions may be influenced by congenital anatomic peculiarities, the first by an abnormally high location of the coronary orifices above the sinuses of Valsalva, and the second by an extension of elastic tissue into the commissures below the upper level of the cusps. The clinical aspects of aortic insufficiency and coronary ostial stenosis are described in Chaps. 223 and 224.

Uncomplicated aortitis is the commonest manifestation of cardiovascular syphilis and the most difficult to diagnose. Indeed, in its early phase it is a pathologic and not a clinical entity. Symptoms are singularly absent, and myocardial function is never embarrassed by aortic syphilis alone. The occurrence of angina pectoris, paroxysmal dyspnea, or cardiac enlargement denotes either syphilitic involvement of the coronary orifices or the valves or some independent complicating disease. The two most reliable signs of uncomplicated aortitis are aortic dilatation and the presence of a ringing tambourlike second aortic sound with or without a systolic murmur. Both signs are found in other conditions, such as hypertension and arteriosclerosis, and hence have little diagnostic significance unless these disorders are absent. Dilatation of the aorta in syphilis becomes apparent only when a sufficient amount of elastic tissue has been destroyed. Aortic widening can also occur with advancing age, in arteriosclerosis, and in hypertension. Similar auscultatory signs are frequent in hypertension, advanced arteriosclerosis, and in conditions giving rise to an overactive circulation.

Uncomplicated aortitis may be diagnosed in a patient known to have syphilis who has had little or no treatment in the early phase of the infection and who presents the auscultatory signs or widening of the aorta, especially in its ascending portion, if the disturbing complications listed above are absent. It is the exceptional patient who meets all of these criteria. The vast majority of cases of uncomplicated syphilitic aortitis cannot be recognized with certainty by present methods.

Syphilitic *aneurysms*, like aortitis, occur with diminishing frequency from the ascending aorta distally toward the abdominal aorta. They may be *single or multiple*, diffuse or sharply localized, fusiform or saccular, *smooth walled or filled with large organizing thrombi*. Aortic aneurysms burden the myocardium only indirectly *as a result of rupture* into or compression of the pulmonary *artery*, atrium, or *ventricle* or, as in the case of aneurysms of the sinuses of Valsalva, by distortion of the aortic valve cusps. Sudden death usually follows rupture with bleeding into the pericardium, bronchi, esophagus, or mediastinum. Many large aneurysms are surprisingly symptomless. In most instances chronic disabilities develop from compression, displacement, erosion, or interference with the circulation in neighboring structures.

The clinical picture is dependent on the size and site of the aneurysm and the direction in which it projects. Aneurysms which bulge anteriorly, particularly those located in the ascending aorta, are relatively asymptomatic, and signs when present are related to the mass itself, i.e., visible pulsations or pulsating tumors, widening of the area of percussion dullness, or shocks, thrills, and systolic murmurs at the base of the heart. In advanced cases the anterior chest wall may be deformed. Aneurysms of the arch and those pointing posteriorly and medially are more likely to produce symptoms and signs. Compression of bronchi attended by chronic cough, atelectasis, hemoptysis, and pneumonia recurring in one lobe frequently mimic the picture of malignancy. Confusion is often increased by evidences of impingement on neighboring structures, such as hoarseness from paralysis of the recurrent laryngeal nerve, phrenic nerve palsy, dysphagia, or venous distention in the neck, upper chest, and arms secondary to compression of the superior vena cava. Horner's syndrome, radicular pains, bone erosion, and bone pain simulate metastatic lesions in the spine. A tracheal tug or marked inequality in radial and carotid pulsations points to aneurysm rather than tumor. Aneurysms of the descending aorta in the region of the diaphragm may give rise to annoying radicular pain and occa

sionally to hypertension and uremia due to renal ischemia

Syphilis is the commonest known cause of chronic obstruction of the origins of the major arterial trunks in the aortic arch It is observed in association with diffuse or fusiform dilatation of the aorta more often than with saccular aneurysms The manifestations may vary ranging from symptomless anisosphygmia to complete obliteration of the subclavian and carotid pulses (*pulseless disease*) Syncopal seizures visual impairment and trophic alterations in the lens and iris may appear but collateral circulation is usually sufficient to prevent severe ischemic changes In rare instances prominent collateral arterial channels may develop over the chest similar to those observed in coarctation of the aorta, except that the direction of flow is reversed (reversed coarctation) Diastolic murmurs of extracardiac origin may sometimes be heard over partially occluded vessels at the base of the heart Nonsyphilitic causes of the chronic obstructive aortic arch syndrome which have to be considered in differential diagnosis are healed dissection of the aorta trauma polyarteritis and arteritis of unknown cause (*Takayasu's disease*) which affects young females predominantly

ARTERIOSCLEROSIS OF THE AORTA

Arteriosclerosis is the most common affection of the aorta The factors which are believed to contribute to its development are increased intravascular tension disturbances in circulating lipids affections of the nutrient vessels and the ill defined changes associated with aging (see Chap 46) The aorta usually becomes dilated elongated, and tortuous Arteriosclerotic aneurysms are relatively uncommon and are more likely to affect the descending aorta Intimal changes range from microscopic deposition of lipid material to pronounced thickening and formation of large atheromatous nodules or plaques Secondary changes may develop in the form of necrosis small hematomas calcification and ulceration

Arteriosclerosis of the aorta is generally symp

tomless Rigidity of the vessel wall leads to an increase in pulse pressure manifested by a rise in systolic pressure the diastolic remaining unchanged or declining slightly Atherosclerotic changes in the abdominal aorta which compromise nutrient vessels of the lower cord may give rise to weakness in the legs or to paraplegia Many arteriosclerotic aneu rysms cause no difficulty except for the anxiety aroused by the palpable pulsating abdominal mass Arteriosclerotic aneurysms can rupture spontane ously usually into the retroperitoneal space or more rarely into the peritoneum This diagnosis should be entertained in any elderly patient with severe persistent backache accompanied by pallor and evidence of acute blood loss Frequently the pain radiates along the sciatic nerve or simulates renal colic Rupture into the intestinal tract can result in massive intestinal hemorrhage Perforation into the vena cava gives rise to the local and general hemodynamic signs of a large arteriovenous com munication

Thrombosis of the aorta may be secondary to trauma or to retroperitoneal inflammation or with out apparent cause It occurs more often at the site of an aneurysm an ulcerated atherosclerotic plaque or as a result of retrograde propagation of an embolus which has lodged at the bifurcation The symptoms depend upon the extent of the ob struction and the rapidity with which it develops Gangrene of the legs is more likely to occur after embolism A more common variety the *Leriche syndrome* develops insidiously often over a period of years This disorder is most frequent in young and middle aged males and is manifested by inter mittent claudication in the buttocks and thighs diminution in femoral pulses muscular atrophy weakness of the legs and occasionally by failure of penile erection The legs are usually pale and cool but unlike the situation in occlusive disease of peripheral arteries gangrene and trophic changes are rare except as terminal complications The thrombosis may extend to the mesenteric or renal vessels resulting in visceral infarction or uremia The development of collateral circulation in the abdominal wall sometimes gives rise to a picture which mimics coarctation of the aorta at an unusual site in which notching of the ribs is absent The thrombosed aorta can often be palpated as a hard pulseless cord Calcium deposits are generally demonstrable in the abdominal aorta in thrombosis and not in coarctation

An arteriosclerotic aneurysm may be identified roentgenologically by the presence of calcific densi ties which outline the dilated walls Changes in lumen in the lower abdominal aorta can be visual ized by special angiographic techniques employing intraaortic or intraarterial injection of contrast media

Recent progress in the field of vascular surgery has made it possible with acceptable risk to re construct or bypass the diseased aorta and major branches Aortectomy and grafting have largely replaced older methods designed principally to strengthen the wall It is the treatment of choice for the thrombosed aorta the symptomatic aneu rysm and the rapidly growing symptomless aneu rysm provided that the renal arteries are spared With improvement in techniques the indications for operation will probably be extended to include the asymptomatic aneurysm that is discovered on routine examination

DISSECTING ANEURYSM

Dissecting aneurysm of the aorta has been re corded on the average of once in about 380 ne cropsies It has been observed frequently as a complication in coarctation of the aorta and more rarely in pregnancy the *Marfan syndrome* (see Chap 261) and in atherosclerosis The disease is almost invariably associated with degeneration of the aortic media of the type described first by Erd heim as cystic medionecrosis This medial defect apparently provides a weak point into which vasa vasorum may rupture particularly under conditions of increased intravascular tension The hemorrhage may dissect proximally into the sinuses of Valsalva or distally along the entire length of the aorta and eventually perforate externally through the adven titia or reenter the aorta through an intimal rupture The whole circumference or only segments of it may be dissected some branches may be skipped and others which arise further downstream may be involved

The exact etiologic sequence is unknown Hyper tension is present in most cases and is probably an important contributory factor There is evidence that the primary disturbance may at times be oc clusive or inflammatory disease of the vasa vasorum The pathologic picture has been reproduced ex perimentally by destroying a segment of the adven titia rich in nutrient vessels Intimal rupture is not universally present and cannot be considered to play an essential role in pathogenesis

Dissecting aneurysm occurs predominantly in middle aged and elderly persons and affects males more often than females The symptoms signs and differential diagnosis are considered in Chap 4 The diagnosis can be suspected on clinical grounds The main features are the character of pain the evidence of interference with arterial flow in various aortic branches widening of the aorta and the evidence of terminal perforation The major features of the pain which when present help to distinguish it from myocardial infarction are the attainment of

peak severity at the onset its persistence and its wide radiation to areas seldom affected in infarction such as the back lower abdomen legs or testes If the patient survives the initial period the pain may subside spontaneously to reappear as the dissection progresses

The blood flow may be impaired in any of the branches of the aorta from the root to the bifurcation causing reduced or absent arterial pulsations in the arteries of the neck abdomen or extremities The manifestations may simulate a cerebrovascular accident ischemic myelopathy renal infarction with malignant hypertension mesenteric thrombosis pancreatitis bleeding peptic ulcer and peripheral embolization

Dyspnea and hemoptysis may mimic pulmonary infarction Myocardial infarction may occur in the rare instances when the dissection involves the coronary ostia

Distortion of the aortic valves gives rise to signs which simulate syphilitic aortic insufficiency and aneurysm Low grade fever leukocytosis and elevated sedimentation rate are commonly present Perforation of the adventitia may occur anywhere along the course of the aorta or its main tributaries resulting in hemorrhage into neighboring structures Perforation of the aorta near the root usually results in hemopericardium and cardiac tamponade The ensuing clinical picture resembles closely that of myocardial infarction with shock distended neck veins and widened area of cardiac dullness Although rupture into the pericardium may lead to S T segment and T wave changes the characteristic electrocardiographic pattern of acute myocardial infarction is absent except in the rare cases when the coronary ostia are involved by the dissection Pulsations of the sternoclavicular joints and the presence of unusual sounds at the base of the heart point toward aortic dissection The latter may be of three types (1) the to and fro murmurs of aortic valve distortion known not to have been present prior to the onset of pain (2) the periaortic friction rub (3) a variety of adventitious sounds probably produced by escaping blood

Pain followed within minutes or hours by signs of arterial occlusion suggests dissecting aorta rather than embolization from myocardial infarction When the cephalic trunks are involved unconsciousness results In the absence of hypotension or arrhythmia this would be extremely rare in myocardial infarction The maintenance of an elevated arterial pressure favors dissecting aneurysm rather than myocardial infarction However marked decline in arterial pressure can occur in both conditions The diagnosis is confirmed when rapid widening of the aortic shadow is detected on successive x ray films Angiocardiogram may reveal the distortion in the aortic lumen and corresponding thickening in the wall but the patient is usually too ill to permit such manipulations

Most patients die within a few days Prolonged survival in some cases for years has been reported in individuals in whom the dissecting process is directed along a plane close to the intima and terminates in one or more perforations back into the lumen of the aorta forming a multichanneled vessel This circumstance has suggested an operative treatment in which an opening is deliberately made between the normal lumen and the dissecting channel in the thoracic portion of the descending aorta At the same time the distal portion of the dissected channel is closed There is a rational place for the use of antihypertensive agents in this disease

Eugene A Stead Jr

SYMPTOMS AND SIGNS POINTING TO PERIPHERAL VASCULAR DISEASE

History and Physical Examination

One should suspect peripheral vascular disease in a patient with the following symptoms and signs

1 Pain in an extremity which is induced by exercise and relieved by rest Pain which is influenced by posture is localized to one digit, is unilateral or is paroxysmal

2 Impaired pulsations of peripheral arteries
3 Abnormal color of the skin particularly when affected by raising or lowering of the part
4 Gangrene ulceration impaired nail growth scleroderma excessive calluses or paronychial infections
5 Abnormal pulsations enlarged veins or edema
6 Unusual warmth or coldness
7 Swelling atrophy or difference in length of extremities
8 Auscultatory evidence of arteriovenous fistula
9 Localized systolic murmur over a large peripheral artery
10 Cyanosis of digits when immersed in cold water
11 Peripheral neuritis

If the above signs and symptoms are absent peripheral vascular disease need not be considered

The arteries capillaries veins and lymph vessels may be involved separately or in varying combinations The disturbances may be from organic disease of the vessels or from abnormal constriction or dilatation caused by dysfunction of the autonomic nervous system

DISTURBANCES IN ARTERIAL FUNCTION

Special Points in History and Physical Examination

Arterial insufficiency causes disturbances in nutrition to the part The following points in the history and examination are to be noted

History of Sensitivity to Cold with Blanching or Cyanosis of Digits On examination the part with arterial insufficiency may be colder than the corresponding part of the opposite extremity

Symptoms of Muscle and Nerve Ischemia Pain which develops in the muscles of the foot or calf on walking and disappears on rest is called intermittent claudication If exercise is continued after pain is present the muscles may become tender In more severe ischemia of the leg pain may occur at rest and be relieved by dependency The pain of ischemic neuritis is severe and diffuse with severe exacerbations Sharp shooting pains may dart through the entire extremity The acute paroxysms are apt to occur at night

State of Peripheral Vessels Presence or absence of femoral popliteal dorsalis pedis and posterior tibial pulses is noted Gangrene of the digits may occur without disturbances in these pulses In the absence of a palpable pulse the skin may show no evidence of malnutrition

Murmurs over Peripheral Vessels Pistol shot sounds are heard over the major vessels when the diastolic pressure is low and the stroke output high Localized systolic murmurs are heard over areas of narrowing produced by either disease of the blood vessel or by external pressure When the vessel is narrowed the local points of stenosis produce a murmur similar to that heard in aortic stenosis If the diastolic pressure below the point of narrowing is low either because of poor collateral circulation or because of wide vasodilatation produced by exercise a continuous murmur may be heard With this exception and that of venous hums continuous murmurs are commonly the result of an arteriovenous communication

Blanching on Elevation Redness and Cyanosis on Dependency On elevation to a 90 angle the part becomes pale and at times white The extent of the pallor indicates the extent of the arterial insufficiency If only the toes or a part of a toe is involved the pallor is limited to the ischemic area The color returns slowly on lowering the part to *heart level* The pallor occurs on elevation because the blood in the capillaries and venules drains out of the part by gravity and because the effective arterial pressure is lowered by having to overcome the hydrostatic force of a column of blood extending from the heart level to the elevated part Some pallor on elevation will occur in a normal foot but the pallor of arterial insufficiency is much more marked

When the part hangs down the blood flow is increased temporarily over the horizontal position because the hydrostatic pressure is added to the pressure created by the heart The increase in arterial pressure is effective until the veins fill Then it is opposed by an equal column of blood on the venous side and the pressure differential between artery and vein returns approximately to the differential present in the horizontal position The minute vessels of the part being in a state of chronic injury because of an inadequate circulation are dilated When these vessels first fill they are red Varying degrees of cyanosis gradually develop because of the slow blood flow

Atrophic Changes in Skin and Edema The skin becomes thin and atrophic Slight edema with loss of normal wrinkles is common If the patient keeps the foot dependent day and night to relieve pain pitting edema may develop from the combination of a high capillary pressure from dependency and the damaged state of the capillaries caused by ischemia

Gangrene

Infection Devitalized tissue offers a good place for infection to spread When peripheral neuritis is present infection may be more prominent than ischemia Osteomyelitis may occur

Neurologic Examination Peripheral neuritis is a common complication of diabetes Buerger s disease periarteritis nodosa and arteriosclerosis may cause neuritis because of the interference with the blood

supply to the nerves In periarteritis motor paralysis as well as sensory loss and pain is common

Occupation There may be a history of unusual exposure to cold and dampness Use of the pneumatic hammer has been said to cause Raynaud s phenomenon

Determination of Cause of Arterial Circulatory Insufficiency If the findings are those of arterial circulatory insufficiency it must be determined whether the insufficiency results (1) from occlusive disease entirely (2) from overactivity of the sympathetic nervous system (3) from abnormal reaction of the blood vessels to cold, (4) from the effect of cold agglutinins or cryoglobulins on the physical state of the blood or (5) from a combination of mechanisms The constrictor effect of the autonomic nervous system may be removed by paravertebral block of the appropriate sympathetic ganglion with procaine or by release of vasoconstrictor tone by body heating In either method the subject, with body exposed is placed in a cool room (temperature 18 to 20 C) The body temperature may be raised by enclosing the trunk in a heating cabinet or by immersing two uninvolved limbs in water baths at 43 C for 40 min When vasodilatation is produced in the upper extremities by body warming or by blocking of the sympathetic ganglion the temperature of the digits rises rapidly to between 30 5 and 33 C If the temperature rises to between 27 and 29 C there is moderate organic vascular disease If no rise occurs or if the temperature falls advanced local arterial disease is present. Body warming is the simplest and most effective method of relieving vasoconstrictor tone in the upper extremities It fails occasionally in the lower extremities Therefore if full vasodilatation does not occur paravertebral block is indicated in the lower extremities

ORGANIC OBSTRUCTION

Balance between Vessel Obstruction and Vessel Formation Obstruction of a large artery is a strong stimulus for new vessel formation and collateral circulation The symptoms produced represent the result of the balance between these two processes Complete obstruction of the aorta below the renal vessels which occurs slowly may produce no symptoms or the picture of impotence and thigh claudication The extremities may appear normally nourished When skin involvement becomes marked, little blood vessels are usually thrombosed This may be primary small vessel endarteritis as in diabetes or it may be secondary small vessel thrombosis secondary to occlusions higher up Gangrene with normal pedal pulses indicates small vessel disease Intermittent claudication with normal appearing vessels and absent popliteal or femoral pulses suggests larger vessel obstruction, which is frequently segmental

Peripheral Arteriosclerosis The etiology and pathology of peripheral arteriosclerosis have been discussed in Chap 228 The history and physical findings are those of arterial insufficiency The diagnosis is based on the following factors

1 Age of the patient It usually occurs after fifty

2 Sex Males are more commonly affected than females

3 Diabetes The incidence of arteriosclerosis is increased in patients with diabetes

4 Evidence of arteriosclerosis is usually present bilaterally although the symptoms may be unilateral

5 There are no symptoms of arterial disease in the upper extremities

6 The arteries as seen by x ray are frequently calcified

7 In patients with diabetes the small vessels may be occluded although the larger vessels are only moderately diseased Local gangrene of the skin of the toes may occur even though the rest of the foot is warm

8 In patients with diabetes neuropathy is common

Thromboangiitis Obliterans This condition was described fully by Buerger in 1908 It is an obliterative vascular disease affecting chiefly the peripheral arteries and veins of males in early adult life The etiology is unknown It is more common in Jews The disease involves primarily the blood vessels of the extremities Involvement of other vessels occurs only after extensive lesions have developed in the extremities Usually the process begins in medium and small sized arteries and affects large arteries such as the femoral and brachial, only in the late stages and in severe progressive disease Veins are involved less commonly The lesion is a nonsuppurative panarteritis or panphlebitis and is segmental leaving normal vessels between diseased segments Thrombus formation follows in which recanalization may occur The lesions come in crops producing complete and usually permanent obstruction followed by the development of extensive collateral circulation The history and physical findings are those of arterial insufficiency or superficial phlebitis The diagnosis is based on these considerations

1 Age Onset is usually between twenty and forty five years

2 Sex. Males predominate in a ratio of 75 1

3 Race Half the patients are Jewish.

4 Migratory phlebitis preceding or accompanying arterial disease

5 Severe pain at rest from ulceration or from ischemic neuritis

6 Absence of calcification as seen by x ray

7 Small vessels of the hands may be involved Thrombosis of mesenteric coronary cerebral or renal arteries is not uncommon

Thrombosis Thrombosis of the larger arteries of the lower extremities is common in the natural course of arteriosclerosis and thromboangiitis obliterans Whether or not dramatic symptoms of acute arterial insufficiency appear will depend on the degree of collateral circulation which has developed Gradual narrowing of a major vessel may progress *unnoticed to complete occlusion because the symptoms* of arterial insufficiency may not develop until the collateral channels begin to thrombose

Embolus Emboli are usually fragments from more centrally placed thrombi The occurrence of sudden arterial insufficiency without physical findings of marked peripheral vascular disease generally indicates an embolus The common sources are

1 *Mural thrombus from the left atrium in a* heart with chronic auricular fibrillation

2 Mural thrombus from the left atrium in a heart with mitral stenosis and commonly but not necessarily with auricular fibrillation

3 Mural thrombus from myocardial infarction of the left ventricle or more rarely from acute or subacute myocarditis

4 Thrombi on valves from subacute or acute bacterial endocarditis

Less common sources are

1 Thrombi in the aorta or its large branches

2 Venous thrombosis in patients with a right left shunt from congenital heart disease

3 Venous thrombosis causing pulmonary embolization right heart failure and passage of clot through patent foramen ovale

4 Myxoma of left auricle

Emboli are likely to lodge at the bifurcation of large vessels A saddle embolus riding on the bifurcation of the aorta may cause circulatory insufficiency in both lower extremities The signs of circulatory insufficiency are usually considerably distal to the embolus because of the effectiveness of collateral circulation The degree of circulatory impairment caused by arterial obstruction and that caused by secondary arterial spasm cannot be de*termined on inspection* The effects of paravertebral block must decide this question The local examination reveals the symptoms and signs of arterial insufficiency Loss of motion and of sensation may occur rapidly Pain has been discussed on page 64 At first there is no pain at the site of the embolus but tenderness may develop after a few hours as the embolus sets up a local inflammatory reaction in the vessel

Exposure to Cold Trench Foot Extremities with normal blood vessels are injured by prolonged exposure to cold Dependency and wetness combined with cold cause tissue damage even though actual freezing of the tissues does not occur On warming the injury results in extreme vasodilatation with swelling of the part because the capillaries have been damaged Later true capillary flow in the skin may cease because of capillary stasis and thrombosis although flow continues through AV communications This gives the clinical picture of superficial gangrene in a warm part Whether complete recovery or gangrene occurs depends upon the extent of the injury Persistent tenderness because of *fibrosis and ischemic neuritis* may develop

Obstruction of Main Arterial Trunk by External Pressure or by Syphilitic or Dissecting Aneurysms Broad insertion of the scalenus anticus muscle with or without cervical rib is a rare cause of Raynaud s phenomenon or organic arterial occlusion The vascular disturbances may be reflex from compression of a portion of the brachial plexus At times trauma *from compression of the artery causes thrombus for*mation with or without embolic phenomena distal to the area of injury

Persons who sleep with their arms hyperabducted above the head or whose occupation causes them to work with their arms hyperabducted may develop numbness and tingling from occlusion of the subclavian axillary vessels Usually discomfort causes the arms to be moved to a different position but gangrene of the fingers has been reported in some cases

Syphilitic aneurysm or dissecting aneurysm may cause obstruction to the main artery supplying the limb

SPASM OF ARTERIES AND ARTERIOLES

Raynaud s Disease and Raynaud s Phenomenon *Raynaud s disease is idiopathic bilateral paroxysmal* contraction of the arteries and arterioles of the digits usually without local gangrene The primary fault seems to be a local sensitivity of the digital vessels to cold The attacks are precipitated by cold or emotion and are relieved by warming Raynaud s phenomenon consists of paroxysmal attacks of ischemia of the digits occurring in the course of other diseases such as scleroderma thromboangiitis obliterans cervical rib arteriosclerosis crutch paralysis and pneumatic hammer disease Diagnosis of Raynaud s disease from the history and examination is made from the following points

1 Sex Females are affected much more often than males

2 Age It is less common before puberty and after forty though it may occur at any age

3 Bilateral and symmetric involvement of digits It is more common in hands than in feet

4 Attacks of cyanosis can be reproduced by immersion of hands in cold water or by cooling the

body rapidly by a cool shower The digital arteries and arterioles contract The finger becomes blue if the minute vessels remain dilated pale if they contract On rewarming, reactive hyperemia occurs

5 If the disease is of many years duration small superficial areas of gangrene may occasionally be present

Diagnosis of Raynaud s phenomenon is made if the above findings are noted in conjunction with organic arterial disease scleroderma cervical rib or history of the use of a pneumatic hammer In the beginning it is frequently impossible to differentiate between benign Raynaud s disease and progressive scleroderma with Raynaud s phenomenon

Scleroderma This is a diffuse disease of the collagenous system with skin and visceral manifestations The etiology is unknown Raynaud s phenomenon is frequently seen before the characteristic skin changes occur In many instances the skin changes are localized to the distal portions of the extremities (acroscleroderma) The skin becomes board like and is bound down to the underlying tissues Decreased sweating increased pigmentation and calcification of the skin occur Gangrene of the digits with marked shortening of the phalanges is not uncommon (sclerodactylia) Involvement of the esophagus heart and lungs may occur early or late in the disease

Ergotism Spasm of the arterioles with thrombosis and gangrene is produced by ergot poisoning In past times it was seen in epidemic form as the result of the contamination of rye with ergot fungus (*Claviceps purpurea*) It is occasionally seen after the repeated use of ergot to induce abortion or after the use of ergotamine tartrate for pruritus

Reflex Spasm Any painful area in the extremities may cause symptoms and signs of ischemia from stimulation of the autonomic nervous system The ischemia of embolus or thrombus is intensified by reflex activity Ischemia from organic disease of the vessels from arteriosclerosis or from thromboangiitis obliterans may be intensified by active vasoconstriction mediated through the autonomic nerves

Disturbances in Small Vessels from Changes in Blood

Changes in the physical state of the blood may cause small vessel obstruction Patients with sickle cell anemia are prone to multiple thromboses The leg ulcers seen in this disease are probably an example of small vessel thrombosis on the basis of mechanical obstruction caused by the sickled cells When the titer of cold agglutinins is high exposure to cold may cause Raynaud s phenomenon The development of globulins which precipitate in the cold (cryoglobulins) in patients with leukemia or myeloma may also cause Raynaud s phenomenon

PROGNOSIS IN DISEASE OF ARTERIES

The prognosis depends upon the age of the patient the rate of progression of the primary disease and the degree of the development of the collateral circulation In *arteriosclerosis* the patients are elderly the coronary and cerebral vessels are apt to be affected by the disease and all the vessels of the extremities are usually diseased. Once gangrene develops, the chances of saving the extremity are not good

In *thromboangiitis obliterans* the prognosis for life is usually good If symptoms are present which indicate that visceral vessels are involved the prognosis becomes more guarded The chances of losing a limb are more difficult to estimate Fingers are occasionally lost the hand almost never One or both lower limbs are more frequently lost The clinical course is very variable In some patients there is no further progression after one or two episodes of arterial occlusion In others the disease is moderately progressive with long periods of relative quiescence between periods of arterial occlusion The progression of the disease exceeds the formation of collateral circulation, and eventually damage to the vascular tree is moderate to severe In time new lesions may cease to develop In certain patients occlusion of large arteries occurs with severe persistent arterial insufficiency or gangrene In a few the disease is rapidly progressive and gangrene develops in two or more extremities Some authors state that the disease does not progress if the patient stops smoking

In *arterial obstruction* from an embolus or thrombus the prognosis is greatly influenced by age and the general condition of the patient The embolus would appear to have the best prognosis because the peripheral arterial tree might be undamaged. However this assumption is modified by the fact that the embolus frequently comes from a mural thrombus caused by congestive failure or myocardial infarction and the mortality and development of gangrene in embolus and thrombosis are approximately the same

In *Raynaud's disease* as defined in this discussion the prognosis is good by definition Complications are rare and the digits are not lost In *Raynaud's phenomenon* accompanying other disease the prognosis is that of the primary disease Thus in scleroderma associated with Raynaud s phenomenon the outlook depends on the extent and rate of progression of the scleroderma. This is true whether the sclerodermatous changes are generalized or are still localized to the extremities

TREATMENT OF ARTERIAL INSUFFICIENCY

Chronic Arterial Insufficiency Since the etiology of arteriosclerosis and thromboangiitis is not known treatment directed toward prevention or removal of the primary factors is not possible In segmental obstruction of the femoral and iliac arteries intimal stripping and grafting offer new hope for improving the circulation

General Care Three points in general care should be stressed

LOW FAT DIET IN ARTERIOSCLEROSIS Many patients with arteriosclerosis have high serum cholesterol values There is evidence that the cholesterol levels can be lowered in many instances by a low fat diet if it is followed over long periods This offers the only direct approach to treatment of the arteriosclerotic process itself

DIABETES In any patient over forty with peripheral vascular disease the possibility of diabetes mellitus should always be remembered and a fasting blood sugar level determined even if there is no glycosuria

COMPLETE ABSTINENCE FROM TOBACCO The course of thromboangiitis is modified if smoking is stopped completely Many physicians are unwilling to assume responsibility for the care of a patient with thromboangiitis unless the patient consents to give up smoking entirely Most observers advise against smoking in arteriosclerosis although the adverse effects of smoking seem less certain here than in thromboangiitis

Care of Local Areas The care of the local area with circulatory impairment from arteriosclerosis thromboangiitis or damage from exposure to cold is similar The greatest danger is gangrene in the toes This is usually precipitated by *trauma infection* or *burns* all of which can ordinarily be prevented by good foot care Care of the feet means careful washing in tepid water at night keeping the skin pliable with lanolin use of a bland dusting powder to absorb perspiration use of warm finely woven woolen socks in winter careful cutting of the nails with the ends cut straight across to avoid ingrowing nails Epidermophytosis must be treated when present but strong ointments or solutions are to be avoided Soaking twice daily in 1 8 000 potassium permanganate solution is satisfactory Dry heat is contraindicated Remember that sensation may be impaired because of peripheral nerve involvement Heat above the temperature of the blood raises the temperature of a part with impaired blood supply much more rapidly than that of a normal part In this situation the blood acts as a cooling system to lower the temperature of the tissues if this cooling system does not function efficiently burns occur Heating the part by reflex vasodilatation is safe local heat may raise the metabolism without a corresponding increase in blood supply and precipitate gangrene The shoes should fit perfectly and should be broken in gradually If any break in the skin or blister occurs from any cause the patient should go to bed and call his physician Reflex vasoconstriction is to be minimized In the winter there is need not only for adequate protection for the part itself but also for attention to preserving the warmth of the body No local protection will keep the extremities warm if the trunk is cool and the body is attempting to preserve heat

Reflex vasoconstriction may accompany organic occlusive vascular disease If body warming or paravertebral block demonstrates release of reflex tone improvement of the circulation to the extremity by sympathectomy is indicated Some observers have reported improvement after sympathectomy even though paravertebral block caused no rise in temperature Sympathectomy may be followed by gangrene in advanced disease because it may divert the greatly limited supply of blood from the severely ischemic tissues to the more normal tissues of the part

Sympathectomy does not increase the flow of blood through muscles and has no direct effect on intermittent claudication If sympathectomy is performed in patients with intermittent claudication it should be more extensive than is necessary to release the vasoconstrictor tone of the vessels of the skin of the leg and foot A higher sympathectomy may be effective in increasing the circulation in collateral vessels by passing the areas of obstruction

Buerger s exercises are useful They have the disadvantage of being too tiresome to continue for a long period of time They help because when the foot is dependent the effective arterial pressure is increased until the pressure from gravity is counteracted by an equal column of blood in the veins The foot is emptied by raising it just far enough above heart level to produce collapse of the veins and slight pallor It is then returned to the dependent position The ideal conditions are (1) maximum lowering of the foot below heart level leaving it there until the veins are full and (2) the least elevation for the shortest period of time which will suffice to empty the foot When the valves of the veins of the legs are competent walking slowly is an effective form of Buerger s exercises The contraction of the muscles forces blood up the deep veins the venous pressure falls sharply as the muscles relax and the high arterial pressure produced by gravity is effective until the veins fill

Pyogenic infections of the feet and toes are common in patients with impaired blood supply This is particularly true if peripheral neuritis is present

If an apparently gangrenous part is warm infection is playing an important role and intensive penicillin therapy may greatly change the picture Each time the doctor must ask himself Is infection or ischemia the primary cause of the acute episode?

Acute Arterial Insufficiency In the acute circulatory insufficiency caused by thrombosis or embolus *immediate* and repetitive release of sympathetic tone by paravertebral blocks of the sympathetic chain is essential Tetraethylammonium bromide or Priscol may be tried if the necessary equipment for the paravertebral block is not at hand The coagulability of the blood is lowered by the immediate intravenous injection of heparin and after determining the prothrombin time administration of Dicumarol is started by mouth Heparin is continued at 4 hr intervals until the Dicumarol has lowered the prothrombin concentration to effective anticoagulant levels If the arterial insufficiency is the result of an embolus effective anticoagulant therapy must continue for approximately 3 weeks until there has been time for the site of the embolus to be covered with endothelium

Operative removal of an embolus may be considered if surgery is available in the first 8 to 10 hr In most instances the complicating heart disease or generalized vascular disease makes surgery inadvisable

The part should not be elevated The body should be heated but local heat should not be applied to the involved extremity Some authorities advise active cooling or even refrigeration of the part during the interval between the occlusion of the artery and the consideration of surgery

Raynaud's Disease The body should be dressed warmly so that the vessels in the hands and feet will dilate to help dispose of body heat The hands and feet should be protected with warm socks and gloves Minor episodes of "dead fingers" should not occasion alarm If these measures are not adequate Priscol given orally in doses of 25 to 75 mg every 3 or 4 hr is frequently helpful

Raynaud's Phenomenon Adequate heat to the body and protection of the extremities from cold and trauma are important The response of the underlying disease to therapy is more important than the treatment of the vasospasm When associated with scleroderma the prognosis is guarded Priscol has been reported to be effective in controlling the vasospasm Sympathectomy may be tried but the effect is usually temporary Testosterone has been reported to have a favorable effect in scleroderma when given for several months

Amputation The indications for amputation are (1) gangrene (2) uncontrollable infection (3) intractable pain and (4) such complete loss of function from deformity or contracture that the limb is a burden Amputation is a last resort, and conservative therapy has saved many limbs The site of amputation must be at a level where tissue nutrition is good In the last analysis the amount of bleeding at operation and the appearance of the tissues after incision determine whether the stump will be viable Usually clinical observation determines the level of the trial incision but special tests such as the appearance time of intravenous fluorescein and the effect of intradermal histamine may be helpful

DISTURBANCE IN VENOUS FUNCTION

Varicose Veins

Dilatation and tortuosity of the superficial veins of the lower extremities result from constitutionally defective valves affected by postural strain or from the enlargement of the superficial circulation to compensate for obstruction of the deep circulation The obstruction of the deep circulation usually results from deep thrombophlebitis Increased blood flow from an acquired or congenital arteriovenous fistula is a rare cause of varicosities

In a normal subject who stands motionless for a short time the hydrostatic pressure in the leg veins is equal to the height of a column of blood extending from the fourth rib to the level of the vein In a man 6 ft in height the pressure at the ankle is about 105 mm Hg Blood from the foot is returned by the force of the heartbeat and all of the valves are open These pressure relations are the same therefore in valved and nonvalved veins On contracting the muscles of the leg and thigh blood is forced up the extremity by the high intramuscular tension With normal valves it cannot be forced downward or outward into the superficial circulation through the communicating veins The blood in the superficial veins of the leg is not forced upward by the contraction because the skin tension does not exceed the hydrostatic pressure When the extremity is relaxed blood does not flow downward into the muscles because the valves control it Blood enters the veins in the muscles from the arteries and from the superficial veins by way of the communicating veins Backflow from the cava is prevented by valves and the runoff through the communicating veins lowers the pressure in the superficial veins effectively The fall in hydrostatic pressure in the venous system lowers capillary pressure effectively and prevents edema When the valves of the veins are destroyed the venous and capillary pressures are not lowered by exercise Chronic edema petechial hemorrhage poor drainage and infection frequently result

Varicose veins fall into the following groups (1) Simple dilatation of the veins with competent valves The lowering of capillary pressure by exercise is maintained and edema does not result Superficial venous thrombosis in the dilated tortuous vessels may be troublesome (2) Varicose veins with incompetent valves in the superficial veins but competent perforating and deep valves On walking the venous pressure is not lowered unless the superficial veins are prevented from filling from above by local pressure When the superficial veins are correctly obstructed by a tourniquet exercise effectively lowers the venous pressure (3) Varicose veins with incompetent valves in the superficial and communicating systems In many of these patients the varicosities have resulted from thrombophlebitis of the deep veins and the valves of the deep veins are destroyed Exercise has no effect in lowering the venous pressure when walking Brawny edema may mask the superficial varicosities and their extent is rarely realized until the venous tree is visualized by the use of Diodrast Intractable chronic ulcers are common (4) Rarely the deep veins are completely obstructed and the superficial veins are needed to return blood from the limb

Treatment of the first two groups by the combination of high ligation and injection of sclerosing solutions or removal by vein stripping is satisfactory The treatment of the last two groups is less satisfactory and prevention by more intensive treatment of the deep vein thrombophlebitis is the most satisfactory answer Destruction of the superficial varicose veins may be helpful even if the valves of the deep veins are destroyed because the varicose superficial veins are rarely necessary to return blood from the leg Once the condition is present it is beneficial to prevent edema formation by application of external force to counteract the effect of gravity Bed rest with elevation of the part allows healing The application of pressure bandages or of a jelly boot prevents the breakdown of the healed lesion when the patient is up One should remember the magnitude of the hydrostatic force one must counteract when the patient stands Ace bandages are rarely adequate a pure rubber roller bandage 3 in wide and 15 ft long is much more effective

Thrombophlebitis and Phlebothrombosis

Thrombus formation in veins is common Dilated tortuous superficial varicose veins frequently become tender and hard with redness of the overlying skin The inflammatory reaction usually subsides uneventfully and embolic complications are unusual Recurrent superficial venous thrombosis is a common occurrence in the natural history of thromboangiitis obliterans Local trauma from the administration of various solutions and medications is a not uncommon cause of superficial thrombophlebitis Again embolic phenomena are rare

Thrombus formation in veins occurs at times in all acute and chronic infections after operations and after childbirth It is common in patients with chronic debilitation heart failure or carcinomatosis and occasionally occurs in apparently normal persons Venous thrombosis is apt to occur contiguous to areas of local infection or trauma It is seen in the pelvis in puerperal infection and in the prostatic veins after prostatectomy In the majority of instances the thrombus begins in the deep veins of the calf and extends proximally The process may cause very little reaction in the vein wall (phlebothrombosis) and if this is the case the thrombus is particularly prone to break loose and lodge in the pulmonary tree On the other hand the reaction may involve the veins of the entire extremity with the inflammatory reactions extending into surrounding lymph channels (thrombophlebitis) With an extensive reaction the clot adheres tightly to the vein wall and then embolic phenomena are less common

The precise etiology of phlebothrombosis and thrombophlebitis is unknown Slowing of the blood stream seems to be an important factor in thrombus formation Acceleration of the clotting time probably plays a part The role of changes in the vein walls has not been determined In spite of the severe systemic reaction and the evidence of the reaction of inflammation in the extremity in the more fulminating cases no infectious agent has been found

Local symptoms may be absent A rise in pulse rate or an unexplained slight fever in a patient in bed may be the only sign of phlebothrombosis and the condition may not be recognized until an embolus has lodged in the pulmonary artery Several days later tenderness in one or both calves may occur Tenderness in the calf and pain in the calf on dorsiflexion of the foot may be the only sign If the foot is dependent slight edema and cyanosis may be observed Other findings may include a measurable although not always visible increase in the circumference of the calf as compared to the opposite leg slight prominence of the veins increased local warmth or diminished pulsation on the affected side and local pain on compression with a blood pressure cuff at a pressure of 80 to 120 mm Hg

At the other extreme is the painful swollen cyanotic leg of acute thrombophlebitis In this condition the arteries are not involved directly intense reflex vasoconstriction may occur however and at times the arterial pulse is felt with difficulty Fever and leukocytosis are present

Treatment is divided into three parts

1 Prevention of clot formation in the leg veins by early ambulation or by bandaging of lower extremities when the patient is confined to bed and by the use of heparin and Dicumarol

2 Prevention of pulmonary emboli after leg veins are involved Anticoagulant therapy is usually successful Pulmonary emboli continue in an occasional patient and ligation of both common femoral veins or the vena cava becomes necessary (Embolism and infarction of the lungs are discussed in Chap 236)

3 Prevention of destruction of lymphatic vessels and veins which leads to persistent edema and chronic ulcers Pain is relieved and edema clears more quickly when the sympathetic tone is released by repeated paravertebral blocks Anticoagulant therapy may reduce the number of vessels permanently thrombosed Elevation and proper bandaging will minimize the edema Particular attention to bandaging should be given when the patient is allowed to be up

DISORDERS OF PERIPHERAL LYMPHATIC VESSELS

Water and electrolytes which leave the capillaries can reenter the capillaries without difficulty Protein and various forms of particulate matter pass into the lymphatic capillaries If the lymphatic drainage to a part is blocked the extracellular fluid will gradually assume a high protein content The capillary filtrate may contain very small amounts of protein but as the water can be reabsorbed by the blood capillaries and the protein cannot an effective concentrating mechanism is present When the lymph vessels are normal lymph flow depends on muscular contraction respiratory movements transmitted movements from arterial pulsations and to a certain extent on gravity Complete immobilization of the lower extremity in a patient sitting in a chair leads to physiologic lymphatic obstruction

Acute Lymphangitis When bacterial infection in an extremity is not localized the inflammatory products pass proximally along the lymphatic channels The material carried in the lymph channels causes dilatation of the small blood vessels about the lymph vessels and their courses are outlined by one or more red streaks Before chemotherapy was available lymphangitis always carried a serious prognosis because it is a sign of uncontrolled spreading infection Immobilization of the part greatly reduces the rate of spread of the infection by reducing the rate of lymph flow With chemotherapy fear of lymphangitis and the surgery necessary with lymphangitis has largely disappeared

Chronic Lymphatic Obstruction Widespread obstruction of the lymph vessels may result from congenital or familial disorders of the lymph vessels The lymphedema of the familial type is called Milroy s disease Acquired chronic lymphedema results from obstruction of the lymph channels by neoplasm scar operative removal of lymph nodes and fibrosis caused by x ray therapy It may follow low grade lymphangitis from filariasis from lymphogranuloma venereum and from repeated streptococcal infections It may be a complicating factor in certain instances of severe edema following thrombophlebitis

In its early stages lymphedema cannot be distinguished physically from any other form of soft pitting edema On laboratory examination the high protein concentration separates it from cardiac and nephritic edema but not from the fluid of myxedema Lymphedema causes fibrosis in the tissues and in time the tissue becomes hard and brawny The skin may be thick and folded with indolent ulcerations

Treatment of Chronic Lymphedema Early and persistent therapy is important If marked edema is prevented by postural drainage by effective bandaging and by limiting upright activity to periods short of edema formation much of the fibrosis and recurrent infection will be prevented This program calls for persistence on the part of both doctor and patient Acute attacks of lymphangitis can be controlled by appropriate chemotherapy

LEG ULCERS IN PATIENTS WITHOUT PERIPHERAL VASCULAR DISEASE

In a normal subject an injury to the skin of the foot or ankle is much more serious than one to the hand or wrist In the ambulatory patient lesions on the lower leg and foot may heal slowly If healing does not occur promptly the patient should be put to bed and the part elevated If the lesion is allowed to become chronic low grade local phlebitis lymphangitis and arteritis develop Even if the main vessels to the part are unaffected these local changes cause poor tissue drainage and tendency to recurrent infection and ulceration A nonhealing nontraumatic ulcer of the lower leg is an emergency and requires bed rest until healing occurs

SPECIAL DIAGNOSTIC TESTS

The history and physical examination will establish the presence or absence of arterial insufficiency

When the circulation is normal no instruments are necessary to demonstrate the fact The skin shows no trophic changes and does not blanch abnormally on elevation The arterial pulses are palpable If the main artery is occluded by pressure for several min utes release of pressure will cause bright red re active hyperemia Heating of the body causes the extremities to warm and immersion of the part in hot water brings out the capillary pulse Histamine pricked into the skin produces a typical wheal and erythema When there is obvious arterial insuffi ciency these findings are changed as outlined under Special Points in History and Physical Examination When other signs of arterial insufficiency are pres ent it is not safe to attempt to demonstrate the capillary pulse by placing the involved extremity in hot water

Special tests have been of value in understand ing the normal physiology of the peripheral circu lation They have been of use in quantitating the degree of damage caused by pathologic processes and have aided our understanding of the develop ment of collateral circulation They have been use ful in determining in at least a semiquantitative way the effects of therapy in occlusive vascular dis ease

The following tests are useful at times

1 Measurement of skin temperatures in a cool room (18 to 20 C) before and after release of sympathetic tone When the blood supply is de creased by occlusive arterial disease or by reflex vasoconstriction or by both the extremities cool Release of sympathetic tone is accomplished by paravertebral block by spinal anesthesia or by raising the rectal temperature by body warming If the skin temperature does not rise the decrease in blood flow is the result of occlusive vascular dis ease A rapid rise to 30 5 to 33 C indicates normal blood supply An intermediate rise indicates both reflex sympathetic constriction and occlusive vascu lar disease This test has the virtue of simplicity and has proved to be of clinical use

2 Arteriography and venography The arterial tree may be visualized by x ray after the intra arterial injection of Diodrast The exact point of arterial obstruction and the pattern of the collateral circulation can be determined It is helpful in showing segmental occlusion in the iliac and femoral vessels These lesions can now be approached sur gically Visualization of the veins by the injection of Diodrast is occasionally useful

3 Circulation time to the extremities Several methods are available The fluorescein test is the most objective Three ml of a 20 per cent aqueous solution of fluorescein is injected quickly into the antecubital vein and the time of appearance of a greenish yellow glow in various parts of the body is observed When arterial insufficiency is present the appearance time of the fluorescein is prolonged In severe ischemia no fluorescein may appear

4 Oscillometer This is a volume recorder which magnifies the changes in volume which normally occur with each cardiac systole The ordinary blood pressure recording apparatus may be used as a crude oscillometer Refinements of the oscillometer have not increased its clinical usefulness

5 Histamine wheal test If the arterial circula tion is inadequate histamine pricked into the skin gives a subnormal or absent reaction

6 Measurement of blood flow by plethysmo graphic techniques has advanced our knowledge of the circulation but the method is not suitable for routine clinical use

Section 3 The Kidneys

T R Harrison

The modern concept of renal disease began to develop as the result of the classic descriptions of clinical features by Richard Bright Among numerous others who made lasting contributions the names of Magnus Levy (disordered excretion of salt) Friedrich von Muller (concept of nephrosis) Volhard and Fahr (correlation of clinical and pathologic findings) Thomas Addis and Donald van Slyke (natural history of the renal disorders) and Homer Smith (development of methods of testing the various renal functions) are especially noteworthy

The reader will be aided in the interpretation of the discussion to follow by reviewing Chap 19 which deals with principles of renal function and with the important manifestations of renal disorders Pyelonephritis and cystitis are considered in some detail in Chap 144

Before discussing the specific diseases of the kidneys an attempt will be made to clarify certain topics which are frequent causes of confusion

231 GENERAL ASPECTS OF RENAL DISORDERS

John P Merrill

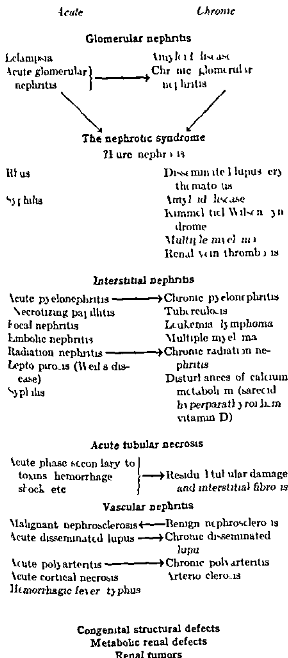
Diagnosis One generality at least may be stated that no particular alteration is characteristic of any particular form of Bright s disease—by whatever cause the end has been reached the organ structure of contracted kidneys is similar The clinician therefore need have no feeling of frustration if at the end he cannot differentiate one from the other by functional means This pronouncement by a pathologist serves to emphasize the fact that exact etiologic analysis of advanced renal disease may be difficult if not impossible not only with regard to manifest functional aberrations but even from the standpoint of the structural changes In advanced renal disease several common types of bilateral processes eventually tend to produce a single clinical picture which is characterized essentially by excretory failure with uremia and generally also by hypertension cardiac enlargement and vascular retinopathy If the patient is seen only at this stage it is often difficult and sometimes impossible to decide whether the initial process was glomerulonephritis nephrosclerosis or pyelonephritis Indeed the destruction of renal parenchyma that is begun as glomerulonephritis frequently is complicated by superimposed pyelonephritis To both of these entities in turn perhaps through the medium of hypertension may be added the changes of nephrosclerosis

From a practical standpoint the evaluation of the patient with frank renal failure should not concern itself primarily with the etiologic nature of the primary process Of much greater importance is the possibility of treatment or reversibility Once it has been ascertained that excretory failure is due to irreparable structural changes treatment at best must be aimed at the containment of the metabolic derangements and the prevention of further renal damage When however there is a possibility that obstruction infection or acute reversible renal damage is responsible for the excretory failure a judicious therapeutic regimen may prolong life sufficiently for the injured kidneys to show marked spontaneous improvement Thus the physician confronted with a case of renal failure must ask himself at once if the underlying process is reversible A partial list of such disorders is included in Table 120 Once it has been ascertained that the renal defect is one of chronic irreversible extensive scarring the events leading to the production *of the* contracted or end stage kidney are mainly of academic interest

Table 120 REVERSIBLE RENAL DISEASE

Acute glomerulonephritis	Renal calcinosis
Acute tubular necrosis	Renal calculi
Acute cortical necrosis	Eclampsia
Acute pyelonephritis	Dehydration
Focal nephritis	Potassium depletion
Embolic nephritis	Congestion (due to heart *failure*)
Syphilitic nephritis	
Obstructive uropathy	

Relationship between Renal Disease and Hypertension Although *certain differences* of opinion exist the more prevalent point of view may be summarized as follows *It is clear* that disease of the kidney *may* induce hypertension This is excep



tional when the renal disease is unilateral but important for it may be amenable to surgical correction Commonly renal hypertension is due to bilateral disease of the kidneys In the author s view the majority of cases of hypertension appear to be primarily attributable not to renal disease but to multiple and as yet poorly defined factors involving the nervous system and the peripheral vasculature It is this form or this stage of the disease to which in our ignorance the term *essential hypertension* is applied Regardless of its cause however hypertension tends to induce disease in the small vessels in certain areas of the body and the renal arterioles and small arteries are particularly susceptible to such damage as a result of increased pressure It may be stated therefore that a large proportion of cases of advanced renal disease particularly in persons over the age of forty stems from hypertension but that most cases of hypertension are not due to primary renal disease Once the hypertensive patient has developed renal disease the latter may aggravate the hypertension which in turn may lead to further renal damage Thus the vicious circle proceeds To the relatively mild clinical picture in which the progress of the disease is slow the term *benign hypertension* is applied *Benign nephrosclerosis* therefore designates the pathologic and etiologic factor in the renal disease When on the other hand the progress of the disease is rapid with degeneration of the systemic and renal vasculature the condition is called *malignant hypertension* and the renal involvement *malignant nephrosclerosis* These terms refer to the rate of progression and to the degree of vascular damage rather than the underlying cause Hence either an individual with primary renal disease and secondary hypertension or an individual with primary hypertension and secondary renal involvement may develop malignant nephrosclerosis and malignant hypertension Some believe that the benign and malignant forms of hypertension represent fundamentally different diseases but the more prevalent view holds that they differ only in degree and rate of progression In general one may assume that the renal disease that occurs following years of elevated blood pressure during which urine examinations have been consistently negative represents extension of the disease process to produce vascular involvement of the kidney This is not a foolproof rule since occasionally renal biopsies in hypertensive patients with just such histories have revealed characteristic chronic interstitial pyelonephritis lending credence to the concept of some workers that most malignant hypertension is due to pyelonephritis

The Concept of Nephrosis Of the many concepts of renal disease that of nephrosis is perhaps the most confusing The word itself is etymologically nonspecific and is applied to a variety of clinical syndromes varied in etiology whose pathologic physiology is more of a generalized metabolic disturbance than that of a primary renal disease The configuration of abnormalities usually seen consists of massive proteinuria marked hypoproteinemia intractable edema and disturbances of lipid metabolism To such a picture the designation *nephrotic syndrome* has been applied and by reason of common usage will continue to be employed in this chapter The various points of view from which nephrosis is regarded and the etiologic factors involved will be discussed in Chap 232 It remains to add that another type of nephrosis *lower nephron nephrosis* has nothing in common with the syndrome discussed above and the term is probably incorrect anatomically Because of common usage however it must be mentioned in context with the more correct and descriptive phrase *acute tubular necrosis*

Renal Impairment and Renal Failure These have been discussed previously (Chap 19) A few of the more salient points may be summarized Diminished excretory capacity of the kidney (renal functional impairment) is characterized in its earlier stages by reduced ability of the kidney to perform standard tests of function The earlier type of impairment is recognized by diminished renal performance of standard tests such as the excretion of dyes maximal concentrating power and the clearance of urea These tests define the potential limits of renal performance but narrowing of these limits may still be compatible with ability to cope with ordinary daily functional demands When however the ability of the kidneys to clear the blood of *metabolites under usual conditions of load* is impaired the term *renal failure* may be applied This concept correctly stresses the fact that the characteristic manifestations of the two states as defined may be determined by the excretory load imposed upon the kidney Thus a high protein intake fever or thyrotoxicosis by increasing the solute load to be excreted may overtax the limited ability of the impaired kidney and cause renal impairment to merge into renal failure In addition the kidney has functions other than excretory such as its role in creatine metabolism and in the production of ammonia and perhaps of glucose These functions too may be impaired by renal failure

Classification of Renal Disease Any classification system for renal disease is necessarily made difficult by the overlapping of one set of criteria on another If for instance one chooses to follow the path of etiology the way may be complicated by the fact that a given microorganism may cause several types of renal disease all of which might be differentiated by a pathologic classification Similarly the morphologic concept suffers from the difficulty

Table 121 CLASSIFICATION OF BILATERAL RENAL DISEASE

Acute	*Chronic*
Glomerular nephritis	
Eclampsia	Amyloid disease
Acute glomerular nephritis →	Chronic glomerular nephritis
The nephrotic syndrome	
Pure nephrosis	
Rhus	Disseminated lupus erythematosus
Syphilis	Amyloid disease
	Kimmelstiel-Wilson syndrome
	Multiple myeloma
	Renal vein thrombosis
Interstitial nephritis	
Acute pyelonephritis →	Chronic pyelonephritis
Necrotizing papillitis	Tuberculosis
Focal nephritis	Leukemia lymphoma
Embolic nephritis	Multiple myeloma
Radiation nephritis →	Chronic radiation nephritis
Leptospirosis (Weil's disease)	Disturbances of calcium metabolism (sarcoid hyperparathyroidism vitamin D)
Syphilis	
Acute tubular necrosis	
Acute phase secondary to toxins hemorrhage shock etc →	Residual tubular damage *and interstitial fibrosis*
Vascular nephritis	
Malignant nephrosclerosis ←	Benign nephrosclerosis
Acute disseminated lupus →	Chronic disseminated *lupus*
Acute polyarteritis →	Chronic polyarteritis
Acute cortical necrosis	Arteriosclerosis
Hemorrhagic fever typhus	

Congenital structural defects
Metabolic renal defects
Renal tumors

In this table the *forms of the major divisions of* renal disease which tend to be acute are listed to the left in the above columns and the chronic forms to the right *The arrows indicate by their direction that acute lesions* may result in chronic disease or in the case of nephrosclerosis that an acceleration of the benign form may appear as acute disease The characteristic lesion of eclampsia is found in the glomerulus so that morphologically and clinically it resembles acute glomerular nephritis although it is etiologically dissimilar described early in the chapter that glomerulonephritis and nephrosclerosis may in late stages have many features in common The separation of acute and chronic renal disease forms a basis for a chronologic *system of classification which has important* prognostic advantage for the clinician Here again however in many forms of renal disease the dividing line between acute and chronic states may not be clear cut and may be described only by such unsatisfactory terms as "subacute" An arbitrary classification embodying all these concepts is presented *in Table 121 in order to orient the reader* to the discussion to follow rather than to introduce a completely adequate classification of renal disease *The nephrotic syndrome which would rest uncom*fortably in any single system of classification is afforded a position of its own in a clinical sense and acute tubular necrosis—a pathologic entity of varied etiology—is similarly treated

232 THE PATHOGENESIS, NATURAL HISTORY, AND TREATMENT OF RENAL DISORDERS

John P Merrill

ACUTE GLOMERULONEPHRITIS

Acute diffuse glomerulonephritis occurs most frequently in childhood It is less common in adult life although well documented cases have occurred *for the first time in patients over sixty years of age* The true incidence of the disease is not known since milder cases often escape detection and this fact must be borne in mind by those who would consider the chronic form of the disease a separate etiologic entity Acute glomerulonephritis is most prevalent between the third and seventh year of life and occurs more commonly in males than in females Occasionally multiple cases of glomerulonephritis occur in families associated with congenital defects such as deafness Climate plays no such important role as it does with rheumatic fever for the incidence is approximately the same in the Northern and Southern United States

Etiology The most important etiologic factor appears to be renal hypersensitivity to extrarenal in*fection particularly of the upper respiratory tract* The commonest infecting organism is the group A beta hemolytic streptococcus of which type 12 and *perhaps type 4 appear to* be particular offenders Although acute nephritis has been reported in epidemics and in small population units such as the *family it is* generally considered a sporadic disease The extreme variability in attack rates for nephritis

following streptococcal infection when compared with the same rather constant relationship (3 per cent) for rheumatic fever suggests that there may be nephritogenic strains of streptococcus and indeed that even the type 12 organism may vary in its nephritogenic capacity Acute nephritis has also been reported to follow pneumococcal pneumonia subacute bacterial endocarditis and gastroenteritis due to the common enteric pathogens In contrast to rheumatic fever glomerulonephritis may follow deep streptococcal infections as well as those manifested by superficial pharyngitis Staphylococcal infections have occasionally been implicated In addition acute glomerulonephritis and the nephrotic syndrome have been reported following generalized reactions to poison oak and in relation to atopic dermatitis In some of these cases the relationship may be based upon the provision of a portal of entry for the streptococcus by the skin lesions Prolonged cold and exhaustion preceding some reported cases of the disease probably serve as factors predisposing to the streptococcal infection rather than as an independent agency The disease has also been reported in relation to other hypersensitivity states such as dermatitis due to an insect repellent after bee sting and in secondary syphilis

These observations suggest that the inflammatory process in acute glomerulonephritis is a manifestation of hypersensitivity to a bacterial product The correlation of the disease with streptococcal antibodies is not clear cut however since it may develop following streptococcal infections whose prompt treatment has prevented the development of circulating antibodies Serum complement is frequently low during the acute attack a fact which has been interpreted as a sopping up of complement at the site of antigen antibody combination The explosive onset of nephritis several weeks after bacterial infection as well as the shorter latent periods with acute exacerbations is in keeping with the concept of hypersensitivity In experimental animals lesions which closely resemble the human disease have been produced by nephrotoxic sera from heterologous species and identical lesions have been produced by the inoculation of homologous kidney extracts combined with streptococci The best working hypothesis is that modification of kidney protein by contact with the streptococcus produces an antigen to which antikidney antibodies are formed

Pathology Grossly the kidneys may appear normal or only slightly enlarged On removal of the capsule the surface may be found to be irregularly flecked with small hemorrhagic areas On microscopic section the fundamental glomerular involvement is revealed The glomeruli are diffusely involved and appear more cellular than usual owing to the proliferation and swelling of the endothelial cells of the tuft In addition polymorphonuclear leukocytes characteristic of the inflammatory process add to the appearance of cellularity Within the capsular space one may see exudate fibrin leukocytes and red blood cells which may also appear in various stages of degeneration further down in the tubules The tubules themselves in the early stage of the disease show little but the nonspecific change of cloudy swelling This may in part be due to disturbance in the supply of blood which comes by way of the narrow partially obstructed glomerulus There may be some edema of the interstitial tissue but early there is little involvement of the arterioles In all probability in those cases in which the disease is mild and followed by clinical cure the regression of these lesions is rapid with little residue save an occasional scarred glomerulus The lesions may however progress in characteristic fashion until the picture resembles that of the so called subacute stage Here the kidneys grossly appear slightly enlarged and there may be scattered deposits of lipid material

Microscopically the glomeruli may appear to be occluded by the mass of proliferated endothelial cells some of which show hyaline change The degree of irreversible occlusion may account for the other changes in the kidney as a result of interruption of the blood supply normally reaching them by way of the glomerulus The hallmark of this stage of the lesion is the epithelial crescent a proliferation of the capsular epithelium seen in various stages of development The tubules now may show marked degenerative changes with fatty degeneration necrosis and atrophy of the epithelium Scattered fibrotic changes begin to appear in the interstitial tissue setting the stage for the third or chronic phase This is marked by scarring which contributes the granular contracted appearance seen in the gross Glomerular changes have now progressed to hyalinization with almost complete destruction of the architecture and in many areas large sections of tubules have been replaced by fibrous tissue Others may show hypertrophic changes best seen when the entire nephron has been teased out The most striking architectural alteration however now appears in the small arteries which show thickening of the intima with marked narrowing or even obliteration of the lumen In this stage the vascular change has become a dominant factor and indeed the pathologic picture may be difficult to distinguish from so called nephrosclerosis

Pathologic Physiology In acute glomerulonephritis is seen one of the rare close correlations between structural change and disturbance of function The obstruction of the glomeruli by inflammatory change and endothelial proliferation would be expected to interfere with the normal filtration

process and indeed function studies in this stage show an excessive reduction in filtration rate and filtration fraction Lesser disturbances of functioning tubular mass are found when the measurements of T_m PAH and T_m glucose are made Renal blood flow is also reduced but to a lesser extent than filtration rate Clinically these changes may be manifest by a small volume of urine (impaired filtration) with a normal or elevated specific gravity (less impaired tubular function) The increased capillary permeability secondary to inflammation is reflected by the protein and red blood cells in the urine Because of the wide distribution of the edema it has been postulated that capillary permeability generally is increased and there is experimental evidence that capillaries other than the glomerulus may be involved There are other explanations for the edema however and the observation that the edema fluid of acute nephritis has the low protein characteristic of transudates would seem to contradict this view The early edema of acute nephritis is probably a function of decreased filtration of sodium plus continuing intake of sodium and water with a possible contribution from increased resorption of the sodium fraction reaching the distal tubules Although hypertension and congestive heart failure may play a role in the edema found later in the course of the disease they almost certainly do not do so in the earliest phases The heart does not appear to be consistently involved in the inflammatory process although changes resembling the Aschoff bodies of rheumatic fever have been found in the myocardium About one third of the patients hospitalized have moderate elevation of blood pressure and about 10 per cent may have severe hypertension This hypertension can be said to be truly renal in origin although ill advised attempts at fluid therapy may contribute to its severity When present edema is largely attributable to positive balances of sodium and it may be aggravated by the rapid onset of hypertension which together with the overhydration may result in frank cardiac decompensation as manifested by an enlarged heart and the classic signs of left ventricular failure Cerebral edema in turn may be aggravated by these factors although an element of vascular spasm has been postulated to account for the convulsive episodes which may occur This vascular spasm difficult as it is to demonstrate may be reflected along with the hypertension by the changes in the retinal vessels In acute glomerulonephritis sudden diureses occur which cannot be accounted for on the basis of slow healing of an inflammatory lesion this fact has been thought to reflect an element of relief of vasospasm and resumption of blood flow in the kidney

General Clinical Picture In mild cases symptoms may be absent and the signs limited to undetected proteinuria and microscopic hematuria In the classic severe case a streptococcus pharyngitis may be followed in 10 days or 2 weeks by the sudden appearance of general malaise headache costovertebral angle pain fever puffiness of the eyes circumoral pallor and the typical urinary findings Occasionally in the less observant patient the dyspnea of congestive heart failure may be the presenting symptom reflecting a somewhat later stage of the disease whose onset had been unnoticed except for vague malaise

Signs and Symptoms Physical examination in mild cases may reveal little except puffiness of the eyes The patient may have a slight elevation of temperature and some evidence of residual pharyngitis There may be some tenderness in the flanks or costovertebral angles and he may complain of vague generalized abdominal distress One third of the patients show an elevation of blood pressure when this is marked—particularly if the patient has been overhydrated—the signs of cardiac failure may supervene In such cases edema may be more marked and the heart may be enlarged to percussion There may be a rapid rate a gallop rhythm elevated venous pressure bilateral rales at the lung bases and pleural fluid The electrocardiogram may show evidence of left ventricular hypertrophy with nonspecific inversion of the T waves across the chest Severe hypertension is frequently accompanied by cerebral manifestations which may take the form of headache drowsiness and vomiting These may progress to muscular twitching and frank generalized convulsions followed by semicoma Blurring of vision commonly accompanies these attacks Although as a rule the eye grounds are normal in acute glomerulonephritis with marked elevation of blood pressure one may see hemorrhages exudate and constriction of the arteries Occasionally frank papilledema may accompany these changes

Examination of the Urine This may be the only method of positively making the diagnosis of acute glomerulonephritis The urinary findings vary from microscopic hematuria with traces of protein to grossly bloody urine or the coffee colored urine which represents the acid hematin residue of the red cells Frequently the urine may be described by the patient as dirty or smoky depending upon the number of red blood cells and the amount of acid hematin present Proteinuria may be the earliest sign and the last one to disappear Markedly concentrated urine may be elaborated in the early stages of the disease but the specific gravity may become normal or low as the renal lesion progresses Low urinary specific gravities also accompany the diuresis that may occur after a period of oliguria In this situation renal function may be good and the decrease in specific gravity the result of the loss of fluid

accumulated during the oliguric stage of the disease A finding pathognomonic of acute glomerulonephritis is the so called blood cast which consists of red blood cells enmeshed in fibrin and protein Hyaline and granular casts may also be present in the early stages of the disease with waxy and fatty casts occurring somewhat later The urine *volume is closely related to the severity of the disease* the greater diminution representing increased severity of the glomerular lesion Total anuria occurs in about 2 per cent of the hospitalized cases and 2 or even 4 days of anuria is not incompatible in children with complete recovery For periods longer than this particularly in the adult anuria in acute glomerulonephritis reflects a poor prognosis The characteristic pattern of renal functional disturbance has already been mentioned Aside from albuminuria and abnormalities in the sediment no disturbance of renal function may be evident by the usual clinical tests In general frank nitrogen retention is seen in the severe form of the disease associated with oliguria and hypertension Less than 5 per cent of the patients become severely uremic during the initial acute attack A normochromic normocytic anemia occurs in many patients with acute glomerulonephritis It may occur in the absence of nitrogen retention but is most marked *when the nonprotein nitrogen is elevated* Inhibition of the bone marrow as well as a hemolytic tendency in the disease accounts for this phenomenon Some degree of hemodilution due to overhydration may also contribute The white cell count is not markedly abnormal unless severe infection is present The degree of derangement of the blood chemical pattern depends upon the severity of the renal failure and the adequacy of therapy rather than upon the disease itself Characteristically during the acute attack the serum complement may be low and the antistreptolysin titer high Some decrease in serum protein levels may be apparent

Diagnosis The diagnosis of acute glomerulonephritis requires the findings of proteinuria and hematuria The blood cell cast is characteristic but may be absent in typical acute cases Changes in the hematologic picture and in the blood chemical pattern as well as the history and physical findings depend to a large extent upon the severity of the disease Other kinds of proteinuria such as orthostatic proteinuria must be considered as well as that which may result from a previously unnoticed subacute or chronic form of the disease Other causes of hematuria are renal tumors nephrolithiasis and bleeding lesions of the lower urinary tract Here the finding of blood casts which can be formed only in the nephron is of great help So called renal irritation may be seen following scarlet fever or during the course of other acute febrile illnesses and is accompanied by microscopic hematuria and proteinuria This cannot be considered acute glomerulonephritis Here time relationship to the original insult severity of the renal lesion and subsequent course may help to differentiate Disseminated lupus erythematosus and polyarteritis nodosa may cause renal lesions which are pathologically clinically and perhaps etiologically similar *and can be differentiated only by other systemic* manifestations of these diseases When an accurate history is not obtained acute tubular necrosis particularly that due to ingested or inhaled toxins such as carbon tetrachloride may faithfully mimic every aspect of acute glomerulonephritis

Clinical Course In the vast majority of children the clinical course is relatively benign and progresses to complete healing Less than 5 per cent of those afflicted die of the acute disease However the mortality is greater and the progression to the chronic state more frequent in adults than in children Death when it occurs is due to uremia congestive heart failure and hypertensive encephalopathy which is usually accompanied by convulsions These manifestations however may all occur in children who then have no evidence of the disease 1 year later

Prognosis There appears to be no relation between the severity of the disease and the prognosis *Indeed the impression is occasionally gained that* in children at least the severe acute forms of the disease are more frequently associated with a better prognosis The prognosis is markedly improved with decreasing age There appears to be no relation between the pattern or the severity of impairment of renal function and the eventual prognosis

Treatment There is no specific treatment for acute glomerulonephritis Bed rest in the early stages appears to be of prime importance Any evidence of residual infection in the pharynx or elsewhere should be promptly treated with the appropriate antibiotics ACTH and cortisone have not proved of value in acute glomerulonephritis and indeed because of their effect upon hypertension and protein catabolism are contraindicated Until the physician is certain about the volume of urine fluid protein and electrolytes should be restricted as indicated under Acute Renal Failure In the absence of nitrogen retention the protein intake should be low (0 5 Gm per kg of body weight) during the acute stage and nonprotein calorie intake as high as possible Although the evidence that a high protein intake is deleterious in acute renal disease in animals is conclusive this fact and the increase of osmotic work in excreting protein metabolites has not been demonstrated in man Nevertheless a moderate restriction of protein has a good basis in common sense under these conditions The anemia that may develop should be treated only when the hematocrit drops below

30 and then by the infusion of small amounts of packed fresh red blood cells because of the danger of suddenly increasing intravascular volume in patients with hypertension and congestive failure Congestive heart failure when it develops should be treated like any other instance of left ventricular failure with particular regard to restriction of fluid and sodium intake The treatment of hypertensive encephalopathy has been described previously on p 1331

The problem of when to begin activity following acute glomerulonephritis is a difficult one The urine should be examined two or three times a week *for protein red cells and casts The last may be* estimated and compared by the semiquantitative method of Addis When nothing but a small amount of protein remains or when a plateau appears to have been reached in improvement the patient may be allowed gradually to be up and about and the effect of mobilization may be followed by these techniques plus the sedimentation rate If there is a marked rise in the sedimentation rate or in the proteinuria or cylindruria bed rest should be resumed and a therapeutic test made again a week or 10 days later If after 3 or 4 months there is no evidence of improvement *the subacute stage has* been reached and treatment may be planned accordingly Every *effort must be made to prevent* recurrence or exacerbation Such measures include *the removal of infected tonsils and other foci of* infection Appropriate chemotherapy should accompany *such procedures Prolonged rest in the* hospital may not necessarily be of optimal value because of the danger of a cross infection Prophylactic sulfonamide or oral penicillin therapy in the subacute stage or for some months after the healing of an acute stage may be of value The potential hazard of sensitization makes the latter method preferable

The manifestations of *eclampsia* are similar to *those of acute glomerulonephritis* although they occur in a totally different setting The characteristic *renal lesion of eclampsia* is extreme narrowing of the glomerular capillary lumen with thickening of the capillary basement membrane and swelling of the glomerular epithelial cells surrounding the capillaries The clinical manifestations of the disease are described on p 1325

CHRONIC GLOMERULONEPHRITIS

Different opinions have been held as to whether chronic glomerulonephritis was a *separate etiologic* entity (type II nephritis) or the result of progressive changes following acute glomerulonephritis Advocates of the first point of view pointed to the frequent lack of evidence for antecedent acute nephritis and to the different pathologic pictures in the two conditions It is most probable however that chronic glomerulonephritis in which no history of an acute episode can be obtained is nevertheless the result of chronic changes following an unrecognized or subclinical attack of the acute disease In this view the pathologic changes in chronic glomerulonephritis represent chronic fibrotic change as a result of progression after an initial acute inflammatory response This view is supported by the fact that the clinical and pathologic picture of chronic glomerulonephritis may be identical whether or not an antecedent history of acute glomerulonephritis is obtained The clinical course may *be characterized by no more than minimal* proteinuria and microscopic hematuria until the symptoms of hypertensive disease or uremia occur Exacerbations may follow upper respiratory disease *or infections elsewhere in the body* or may be secondary to nonspecific trauma such as fatigue *and exposure to cold During such exacerbations* there may be a marked increase in urinary ab*normalities* with hypertension edema and nitrogen retention all of which may improve with bed rest *and treatment* Lacking a *previous history in such* instances it may be difficult to differentiate such *exacerbations from an initial attack* of acute glomerulonephritis The nephrotic syndrome may also *present as the initial manifestation of chronic* glomerulonephritis Renal amyloidosis may cause *chronic glomerular lesions whose clinical manifestations* except for a lesser incidence of hypertension *may simulate any stage of the more common form* of chronic glomerulonephritis

Treatment is confined to the elimination of those factors predisposing to exacerbations of the disease When hypertension or renal failure occurs the treatment is that of the particular complication The combination of hypertension and uremia carries a grave prognostic significance and mitigates against the lasting success of any known form of treatment *for hypertensive disease Patients with chronic* glomerulonephritis may also exhibit the signs of chronic pyelonephritis Low grade infection of this sort is difficult if not impossible to eradicate and the use of multiple antibiotics should be attempted with caution because of the danger of producing drug resistance Acute infection should be treated vigorously *to prevent further destruction* of renal parenchyma

THE NEPHROTIC SYNDROME

Muller in 1905 coined the word *nephrosis* to designate a disease state of the kidneys which was not characterized by *inflammation* and to which he deemed the suffix "itis" to be inappropriate As a descriptive term it represented degenerative disease of the tubules for according to Muller and many

since lesions of the glomerulus were frequently not demonstrable

An increasing amount of evidence indicates that the glomerulus is involved We know for instance that the nephrotic syndrome may be a part of the picture of chronic glomerulonephritis Studies of renal function in nephrosis frequently give evidence of impairment in filtration rate and suggest a pattern similar to that of chronic glomerulonephritis although the history and other findings of the disease may be minimal Amyloid disease of the kidney and intercapillary glomerulosclerosis are both represented by typical lesions in the glomerulus In both the picture of nephrosis may be present Other observers have stressed the lesion of the basement membrane of the glomerular capillary in nephrosis The restaining by new techniques of sections of kidney taken from so called pure nephrosis" has revealed lesions of the glomerular basement membrane previously not recognized For this reason and because the clinical picture of nephrosis may be present in disease states of apparently widely differing etiology the appellation *nephrotic syndrome* is perhaps more appropriate By this is implied the syndrome manifested by massive edema proteinuria hypoproteinemia and (usually) elevation of the serum cholesterol and lipids The fact that the glomerulus may be involved however helps only little in the fundamental understanding of the disturbance itself which remains one of the most complex and fascinating mysteries in medicine

Etiology The nephrotic syndrome may be one of the manifestations of such etiologically different renal diseases as chronic glomerulonephritis amyloid disease of the kidney syphilitic nephritis thrombosis of the renal vein and disseminated lupus erythematosus In children one may see the nephrotic syndrome unaccompanied by anamnestic physical or chemical evidence of any of these diseases The recovery rate among such children is high and in the past the disease would have been labeled pure nephrosis Whether such an entity exists or whether like acute glomerulonephritis in children it is a glomerular lesion which completely heals has not been settled Studies on animals suggest that urinary losses of protein may be the major contributing factor to the entire metabolic derangement

Pathology The pathologic lesion in the nephrotic syndrome depends upon whether the underlying problem is one of amyloid disease syphilis chronic glomerulonephritis or intercapillary glomerular sclerosis In pure nephrosis" the existence of the distinctive glomerular lesion was previously denied Whether in such cases special techniques will decisively demonstrate lesions of the basement membrane is yet uncertain All however agree that there may be degenerative changes in the tubular epithelium with scattered lipoid deposits which in polarized light appear doubly refractile

Pathologic Physiology The functional disturbances in the nephrotic syndrome may be roughly regarded from two points of view—disturbances in renal function and disturbances in fat and protein metabolism The renal component is characterized by excessive retention of sodium and marked proteinuria The best explanation for proteinuria is that these losses are entirely dependent on increased glomerular permeability The protein which appears in the urine is not qualitatively different from the plasma proteins of normal individuals The representation of each fraction however is quantitatively different from the normal The plasma protein disturbance is characterized by a marked hypoalbuminemia The total globulins are increased in the alpha and beta fractions and there is a decrease in the gamma globulins Serum cholesterol and total lipids are elevated and there is said to be a characteristic disturbance pattern in the lipoproteins Plasma amino acid levels tend to be low These latter factors all suggest some defect in liver function Histologically however no lesions are seen in the liver and the clinical tests of liver function show no disturbance It is possible though unproved in man that the renal losses of protein may account for the hypoproteinemia and that the accompanying abnormalities in lipid metabolism may be compensatory " In the full blown nephrotic syndrome however it is difficult by high protein feeding or the infusion of albumin to raise the levels of plasma protein more than transiently and to a minor degree Indeed both of these measures tend to increase proteinuria and the infusion of albumin may be followed by the elimination in the urine of 90 per cent of the infused protein

Hypoalbuminemia by decreasing the plasma oncotic pressure promotes edema as does the decreased tissue back pressure which must obtain in many of these protein depleted patients Transfer of fluid from the intravascular to the interstitial compartment tends to decrease plasma volume Recent evidence suggests that decreased plasma volume may increase aldosterone secretion thus accentuating sodium retention Increased urinary excretion of aldosterone has been found in nephrotic patients Diuresis however apparently may occur without gross changes in plasma volume or colloid osmotic pressure It is possible that the latter changes might not be noticed since a small increase in oncotic pressure would mobilize interstitial fluid which would then obscure the increase in serum protein Nevertheless it has been a frequent observation that improvement in the nephrotic syndrome whether spontaneous or induced by ACTH is accompanied by improvement in these parameters The role of the renal mechanism in edema

formation is likewise not clear Although a decreased filtration rate has been implicated in the formation of edema the filtration rate in the nephrotic syndrome may be reduced normal or even supernormal The renal tubules however tend to retain more of an infused sodium load than do those of normal persons and to excrete a nonresorbable anion with potassium rather than sodium This fact might suggest an adrenal cortical effect possibly that of aldosterone Adrenalectomy in fact has been reported to be followed by large sodium losses even with nitrogen retention and marked decrease in filtration rate

The lipidemia that occurs is striking with high levels of both free and esterified cholesterol and phospholipid fractions The plasma often appears milky Since in the experimental animal repeated plasmapheresis may cause a hypercholesterolemia the relationship of this to the hypoproteinemia might be considered an ineffectual attempt to increase oncotic pressure or as has been suggested increased lipid transport from fat depots to compensate for protein losses The frequent finding of a low basal metabolic rate suggests a reason for the hypercholesterolemia It is difficult however to assess the actual meaning of a low basal metabolic rate because of the difficulty of calculating surface area in the edematous patient There is evidence that thyroid function is normal and that the protein bound hormone may be lost in some quantity in the urine

Patterns of renal function vary with duration and degree of renal involvement There is a tendency however for the filtration fraction to be somewhat depressed

The profound metabolic changes which may be induced in the nephrotic syndrome by the administration of the adrenal steroids or ACTH may throw new light upon the pathologic physiology The diuresis which may occur during the course of treatment or follow its cessation results in massive losses of sodium and edema fluid in increased glomerular filtration rate (although diuresis may occur without increased filtration rate) decreased proteinuria increase in plasma protein and decrease in serum cholesterol Similar changes result from the so called "spontaneous diuresis" Such facts suggest that the glomerulus is a primary site of the disease but that the syndrome is characterized by reversible hemodynamic and metabolic processes early in the course Irreversible organic lesions in the nephron may be eventually superimposed upon the reversible changes

Signs and Symptoms The onset of the nephrotic syndrome depends in part upon etiology In children it may occur rather suddenly with the appearance of generalized edema days or weeks following upper respiratory infection or indeed without any antecedent infection at all In others the onset may be insidious with first dependent then generalized edema and the accumulation of fluid in the serous cavities In the patients with chronic glomerulonephritis or intercapillary glomerulosclerosis (*Kimmelstiel Wilson s syndrome*) the onset may masquerade as or be masked by congestive heart failure Pallor is often a striking feature The generalized edema may be accompanied by anorexia and other gastrointestinal disturbances Marked ascites may be present as well as hydrothorax and both contribute to respiratory embarrassment The skin of the abdomen thighs and lower legs is tense and shiny and may develop splits from which serous fluid may leak or which may act as portals of entry for infection The urine volume is usually scanty with a high specific gravity There is marked proteinuria, with many hyaline casts occasional granular casts and rare red blood cells There may be a slight anemia which becomes more severe with the onset of renal failure The disturbances in plasma protein and lipids have been described Nitrogen retention may occur as the disease progresses to more diffuse involvement of the kidneys The erythrocyte sedimentation rate is characteristically high but this is probably a factor of the lipemia and high globulin rather than evidence of infection Blood pressure is usually normal until the onset of renal functional impairment

Clinical Course The disease may be characterized by spontaneous remissions during which diureses occur and the metabolic abnormalities diminish Over a period of years particularly in children such waxing and waning of the disease picture may be followed by permanent cure In adults however although the disease is not common it frequently terminates in uremia hypertension and heart failure if untreated It is not unusual to see such patients lose their edema with the onset of uremia and severe hypertension Patients with the nephrotic syndrome are unusually susceptible to infections of all types possibly because of a low plasma gamma globulin The pneumococcus and streptococcus are common offenders particularly in the form of pneumococcal pneumonia and peritonitis and were a frequent cause of death before the era of antibiotics A frequent complication is the onset of tender red areas resembling erysipelas on the anterior thighs and abdomen which may be accompanied by fever vomiting and general signs of toxicity Occasionally the abdominal signs may include severe pain generalized tenderness and rigidity and closely simulate acute intraabdominal conditions requiring surgery Such episodes have been termed *the nephrotic crisis* Following such attacks it is not unusual to see a spontaneous diuresis and remission

A drop in plasma amino acids may precede such crises.

Prognosis. About 50 per cent of children with the nephrotic syndrome recover without apparent sequelae. Some of these may have shown signs of renal failure during part of the course of their disease. The remainder, however, go on to chronic glomerulonephritis with its sequelae. The prognosis of the nephrotic syndrome with amyloid disease and Kimmelstiel-Wilson's syndrome is that of the underlying disease process. Syphilitic nephrosis is a curable type of nephrotic syndrome. The onset of hypertension or nitrogen retention in the patient with nephrotic syndrome is an ominous prognostic sign.

The majority of adults show the progression to chronic nephritis. The effect of the adrenal steroids and ACTH upon the ultimate course of the nephrotic syndrome awaits fuller evaluation. We cannot be sure that the striking remissions induced are cures, but there is some slight evidence that a larger percentage of those treated may go on toward permanent healing.

Treatment. This should consist of a diet low in sodium and high in potassium but without drastic salt restriction. The protein intake should be normal, but forced feeding of protein is not apparently of value. Care should be taken to prevent splitting of the tense skin and to avoid infection if this occurs. Prompt treatment with appropriate antibiotics is indicated for the attacks of cellulitis and similar infections. Mercurial diuretics combined with xanthines may be tried for the treatment of edema. Frequently these are ineffective, however, and if so should not be continued in an effort to achieve diuresis with larger doses than those normally employed. Mercurial diuretics should never be used intravenously. It is important, however, to see that proper absorption of the drug occurs from a nonedematous site. The use of cation exchange resins has apparently not been effective, nor is the diuretic effect of the administration of urea worth the distress it causes. Salt-poor concentrated human serum albumin is effective but is prohibitively expensive; its effect is transient, and a large percentage of it is lost in the urinary protein. A transient sodium and water diuresis may follow the infusion of plasma substitutes of high molecular weight such as gelatin, dextran (12 per cent). Until the metabolic handling of dextran is further delineated, however, repeated infusions of large amounts of this substance for the treatment of nephrotic edema cannot be advocated. The use of ACTH may result in a diuresis either during the course of therapy or immediately upon cessation. This occurs in 70 per cent of cases uncomplicated by renal failure in the first or second trials. The diuresis is often accompanied by the metabolic improvement mentioned above. ACTH may be used in the average adult in dosages of 150 to 250 mg a day, given in divided doses intramuscularly. The long-acting ACTH gel preparation may be used in 100 mg daily. Most effective is the continuous intravenous infusion of as little as 25 mg ACTH in 5 per cent glucose and water over a period of 12 hr or longer. Similar results may be obtained by the oral administration of 300 to 400 mg per day of cortisone or hydrocortisone in divided doses. Meticorten (prednisone) in oral doses of 100 to 125 mg per day is equally effective. The physician should be familiar with the complications of steroid therapy which are described elsewhere (p. 585). The treatment should be continued for a 2-week period unless diuresis occurs earlier. Not infrequently, a second or third course will induce diuresis where previous therapy has failed. During the initial days of therapy, the patient may gain weight because of increased sodium retention. This may be minimized in some cases by the use of mercurial diuretics or carbonic anhydrase inhibitors (Diamox). Proteinuria may actually increase in the early part of the program and there may be transient episodes of hypertension. Diuresis may commence on the fifth to seventh day of therapy, or it may not appear until after the drug has been stopped. In the latter instance, the only beneficial result may be the loss of edema, whereas in the former all the metabolic abnormalities may be reversed. Disappearance of proteinuria heralds the most favorable result. The use of maintenance steroid therapy following a continuous course appears well worth while. The drug is given for 4 days a week only, which minimizes the manifestations of hypercorticism. Where proteinuria has disappeared with therapy and maintenance treatment been given, the number of long-term remissions (2 to 3 years) suggests the possibility of "cure." Nevertheless, there is inadequate evidence to ascertain whether after such a period the drug may be stopped without danger of remission. During therapy, supplemental potassium salts in the form of acetate or citrate yielding 20 to 30 mM of potassium per day should be given. Not infrequently, a poor result may be converted into a satisfactory diuresis by the infusion of 12 per cent dextran or of serum albumin 24 to 36 hr following the withdrawal of steroid treatment. ACTH or corticoid therapy is contraindicated in the presence of marked renal failure or hypertension. The induction of measles in nonimmune individuals has resulted in spontaneous diuresis. Treatment of the nephrotic syndrome with typhoid vaccine and with nitrogen mustards has been reported with questionable success. Induced malaria has also produced remissions.

Intercapillary Glomerulosclerosis (Kimmelstiel-Wilson's Syndrome). Approximately 60 per cent

of diabetics of long duration may show the lesion of intercapillary glomerulosclerosis and of these some 5 to 7 per cent may be associated with varying degrees of the nephrotic syndrome Characteristically this form of the nephrotic syndrome occurs in the sixth to seventh decade of life but it may be seen as early as age sixteen It is usually associated with a mild form of diabetes and with hypertension It is well correlated with arteriosclerotic changes elsewhere in the body and particularly with diabetic retinopathy Pathologically the characteristic lesion is a spherical deeply staining acidophilic mass of hyaline material occupying the center of a glomerular tuft Associated arterio- and arteriolonephrosclerosis is a constant finding along with some degree of interstitial and focal fibrosis and tubular atrophy and dilatation The etiology is unknown although experimentation implicates an adrenal cortical factor The administration of cortisone to rabbits made diabetic with alloxan may produce strikingly similar lesions The clinical picture is that of a mild nephrotic syndrome usually accompanied by hypertension and moderate vascular lesions The renal functional pattern shows nonspecific impairment similar to that of chronic glomerulonephritis With the use of polarized light one may find in the urine sediment doubly refractile lipoid bodies with the appearance of bright achromatic Maltese crosses" This is said to be characteristic The prognosis and clinical course are usually determined by the extent of the vascular disease rather than the renal lesions although an occasional patient dies in uremia Treatment is that of the diabetes of the hypertension and vascular disease and of the edema Adrenal steroid therapy should not be employed in such patients

Rarer Forms of Nephrotic Syndrome

Amyloid Renal Disease Involvement of the kidney by amyloid disease may produce the full blown nephrotic syndrome This is common with the secondary type but rare with the primary type of amyloidosis (p 720) Histologically the typical renal lesion is scattered amyloid deposits in the glomerular tuft The disease should be suspected in a patient with enlargement of the liver or spleen presenting the characteristic stigmata of the nephrotic syndrome Classically a previous history of chronic infection is elicited The renal lesion may progress to uremia although hypertension is the exception rather than the rule The diagnosis is confirmed by the demonstration of a positive Congo red test (Chap 91) It should be remembered in this test that a certain amount of the dye may be lost by binding to urinary protein The therapeutic problems are similar to those of the other forms of nephrosis and of uremia when the latter develops

Syphilitic Nephrosis This is a rare disease but important because it is amenable to specific antiluetic therapy The diagnostic points are the presence of the nephrotic syndrome usually of sudden onset in the face of positive evidence by history physical examination and serologic tests of the presence of secondary syphilis Antiluetic therapy is usually dramatic

Renal Vein Thrombosis This is an unusual but well documented cause of nephrosis A history of thrombosis elsewhere and evidence of anastomotic circulation may make the diagnosis

Multiple Myeloma This disorder may produce a typical nephrotic picture associated with myelomatous infiltration of the kidneys renal amyloidosis or both

INTERSTITIAL NEPHRITIS

In this discussion the term *interstitial nephritis* will be used to denote an exudative inflammatory response in the interstitial tissue of the kidney The term *pyelonephritis* for purposes of clarity denotes interstitial inflammation in both the parenchyma of the kidney and the renal pelvis while *pyelitis* signifies the involvement of the renal pelvis alone without spread to the renal parenchyma—a situation which is unusual in infections of any duration The changes of chronic interstitial nephritis usually secondary to pyelonephritis are the most frequent cause of chronic kidney disease in dogs and in man

Pyelonephritis Infection of the renal parenchyma is probably the commonest cause of hypertension and of uremia in women under the age of fifty and is an occasional cause in men The active phase of this disorder may be of the acute type with fever pyuria and bacteriuria or of the cryptic variety with lassitude and positive urine cultures as the principal features Under these circumstances the chief problems are those of identifying and eradicating the infectious agent and these have been discussed in Chap 144 which also includes a consideration of cystitis

In the terminal phase of chronic pyelonephritis all clinical and bacteriologic evidence of infection may be lacking the picture of hypertension uremia and vascular retinopathy may be indistinguishable from that produced by chronic glomerulonephritis or nephrosclerosis Indeed the three disorders or any two of them frequently coexist Occasionally it is possible to demonstrate by x ray that one kidney is much smaller than the other and such asymmetry is strong evidence that pyelonephritis is the primary disease process The recognition of pyelonephritis is usually easy if the patient is followed throughout the course of the disease but is frequently impossible if the subject is not ob

served until the terminal phase of contracted kidney with uremia has appeared

The treatment of pyelonephritis involves three problems (1) eradication of the infection (p 969) (2) management of hypertension (p 1327) and (3) the treatment of acute or chronic uremia as discussed on pp 1367 and 1366

Rarer Forms of Interstitial Nephritis

An acute diffuse interstitial nephritis has been described in association with such infectious diseases as diphtheria scarlet fever and Weil s disease Microscopically one sees an occasional focal but usually diffuse infiltration of the interstitial tissue by plasma cells lymphocytes and polymorphonuclear leukocytes In man such involvement is thought to heal without permanent damage Chronic interstitial nephritis in which similar pathology has progressed to degeneration and atrophy and fibrosis of renal tissue may also be seen Such lesions may follow the chronic infiltration with leukemia cells or the cells of multiple myeloma

The kidneys and renal pelves may be involved by suppurative processes as the result of (1) organisms reaching the interstitial tissues by way of the blood stream or (2) ascending infection from the lower urinary tract either by way of the ureters themselves or of the periureteral lymphatics When the kidney alone is involved by blood borne infections the condition of *focal* or *embolic* suppurative interstitial nephritis obtains This is frequently the result of staphylococcal infection blood borne from suppurative processes elsewhere in the body In bacterial endocarditis septic emboli to the kidney may result in a focal process which is frequently also accompanied by changes resembling those of acute glomerulonephritis Occasionally colon bacilli are found although the colon bacillus appears to be a rare causative agent in this type of nephritis Microscopically multiple small purulent foci are seen which may coalesce to form a larger *renal carbuncle* Occasionally the spread of such an infection to the perinephric tissues results in the formation of a perinephric abscess Here local tenderness or swelling in the costovertebral angle with pain on motion of the trunk (evidence of psoas muscle irritation) may give a clue to the diagnosis

A syndrome has been described following deep radiation to the renal areas which resembles those of acute nephritis and may progress to a picture similar to the chronic stage Changes begin 6 to 12 months after cessation of therapy with proteinuria but no hematuria There are a few such cases that go on to hypertension and azotemia and die in uremia Microscopically one notes a generalized intertubular fibrosis and in the later stages hyaline obliteration of the glomeruli with fibrinoid necrotic lesions of arterioles

Syphilitic Nephritis In less than 1 per cent of the cases of secondary syphilis poorly defined renal lesions occur represented by interstitial accumulation of mononuclear cells and lymphocytes which may encroach upon the tubules The clinical picture may vary from mild proteinuria alone to severe proteinuria and cylindruria with generalized edema and many of the characteristics of the nephrotic syndrome Renal function studies suggest the pattern seen in acute glomerulonephritis All of the abnormal phenomena may be reversed by appropriate penicillin therapy Interstitial lesions are characteristic of the Metabolic Renal Disorders discussed below principally those concerned with disorders of calcium and uric acid metabolism

VASCULAR NEPHRITIS

The term *vascular nephritis* includes several disorders in which the prime etiologic factor is disease of the renal vasculature This in turn usually reflects disease of the systemic vessels

Nephrosclerosis

The characteristic lesion of renal vascular disease is sclerosis of the arterioles manifested particularly by hyaline thickening of the intima of the afferent arteriole of the glomerulus This may be seen in other types of renal disease Indeed its end result —the scarred contracted kidney—is extremely difficult to differentiate from the final stage of chronic pyelonephritis or glomerulonephritis In the benign or slowly progressive form of essential hypertension this intimal thickening results in sclerosis of the arterioles and the resultant narrowing of the lumen compromises the blood supply to the areas supplied This leads to a patchy fibrosis with areas of normal tissue between Characteristically one sees a spotty thickening of the basement membrane of the glomerulus and finally obliteration of the capillary tuft Further tubular destruction and fibrosis result with renal function compromised according to the extent of the damage The end result of the fibrous changes is a contracted scarred kidney These renal vascular changes however do not necessarily reflect vascular changes elsewhere in the body In the malignant phase of *essential* hypertension the characteristic changes are a rapidly progressing endarteritis obliterans with marked thickening (onionskin) of the intima of the arterioles and necrosis of both the media and the intima If the onset is sudden and the progress rapid enough death may ensue before the fibrotic changes decrease the size of the kidney The pathologist then sees a normal sized kidney with the microscopic changes previously described and with its surface in the gross studded with punctate hemorrhages which resemble the embolic flea bitten

appearance Between the extremes of the benign and malignant changes one may see many varieties of structural change including the characteristic lesions of other renal diseases which may result in systemic hypertension Here the vascular lesion probably represents the result of hypertension rather than the underlying disease process

The signs and symptoms are those of hypertension and renal failure There are no specific urinary findings except occasional hematuria, the so-called "renal epistaxis" *The functional change early in hypertension is characteristically an increased filtration fraction, possibly representing constriction of the efferent arteriole* The treatment of nephrosclerosis is the treatment of hypertension and the accompanying renal failure when present The relationship between hypertension and vascular disease of the kidney has already been discussed in some detail (p 13_6)

Renal Arteriosclerosis

In renal arteriosclerosis the larger arteries are involved and this fact probably accounts for the moderate degree of depression of renal function frequently seen in elderly patients without specific disease In the absence of other forms of involvement it is rarely severe enough to cause frank renal failure

Rarer Forms of Vascular Nephritis

The renal lesion of disseminated lupus erythematosus is predominantly proliferation of the endothelium of the glomeruli Thickening of the basement membrane in an irregular fashion results *in the so-called hyaline "wire loop" lesion This* however may frequently be absent in the diseased kidney The early clinical signs and symptoms are predominantly those of the systemic manifestation of the disease Occasionally the nephrotic syndrome may appear Frequently there is marked proteinuria and the urine sediment may yield representatives of all forms of casts a *situation thought by* some to be typical of the disease but not consistently reliable Treatment with ACTH and cortisone which may markedly improve systemic manifestations only rarely helps the renal lesion and occasionally appears to hasten its progress The amelioration of systemic manifestations with adrenal *steroid and antibiotic therapy has resulted in a* marked increase in the number of cases dying in renal failure since this component proceeds unabated At necropsy such treated cases show lesions strikingly resembling those of chronic glomerulonephritis The renal lesions of polyarteritis nodosa resemble those of malignant nephrosclerosis except that there *is more perivascular cellular response* The effect of treatment with adrenal steroids is similar to that seen in lupus

The renal *manifestations of hemorrhagic fever* which were studied at length during the Korean conflict, are those of a generalized vascular disease whose etiology is yet unknown but which is probably infectious in nature Renal functional impairment, when it occurs may be mild and transient or may include prolonged oliguria and uremia The shock phase of the disease undoubtedly contributes to the renal lesion Microscopically the predominant changes are engorgement of blood vessels and *evidence of escape of blood into surrounding tissues* The vascular lesions of typhus fever may involve the kidney with resultant proteinuria and cylindruria which rarely progresses to renal failure

Platelet thrombi in thrombotic thrombocytopenic disease may involve the renal vessels and result in renal failure Occasionally such a case responds temporarily to steroid therapy

Bilateral symmetric cortical necrosis of the kidneys most frequently occurs in pregnancy usually in the setting of preeclampsia. The pathologic lesion *is necrosis of the cortices of both kidneys* occasionally complete but sometimes with wedge shaped areas of intact tissue separating the infarcted tissue The microscopic pathology is characterized by thrombosis of all small arteries and arterioles within the involved portion of the cortex. Although it has *been thought that this syndrome* was *100 per cent* fatal, it is probable that bilateral cortical necrosis is a severe manifestation of vasospasm which in other instances may yield only acute tubular necrosis and that the syndrome is compatible with clinical recovery

CONGENITAL STRUCTURAL DEFECTS

Polycystic Disease of the Kidney This condition is thought to result from embryologic failure of the union of the collecting ducts and the convoluted tubules It is manifested by multiple cysts some of which may be grapefruit size in both kidneys *The growth of these cysts is the result of increase* in size of individual cysts rather than the development of new cyst structures Their growth causes destruction of adjacent normal renal tissue with resulting fibrosis There is a strong familial tendency in polycystic diseases and there may be other cystic abnormalities in the liver and pancreas *Small ("berry") aneurysms of the cerebral vessels* may also occur Although the disease may result in death in childhood, characteristically the patient may do well until the fourth or fifth decades then the first clue to the diagnosis may be the signs and symptoms of hypertension, which occurs in about half the cases or renal failure The striking tolerance *of such patients to* marked renal failure and the length of survival with minute amounts of functioning renal tissue give an important commentary upon

served until the terminal phase of contracted kidney with uremia has appeared

The treatment of pyelonephritis involves three problems (1) eradication of the infection (p 969) (2) management of hypertension (p 1327) and (3) the treatment of acute or chronic uremia as discussed on pp 1367 and 1366

Rarer Forms of Interstitial Nephritis

An acute diffuse interstitial nephritis has been described in association with such infectious diseases as diphtheria scarlet fever and Weil's disease Microscopically one sees an occasional focal but usually diffuse infiltration of the interstitial tissue by plasma cells lymphocytes and polymorphonuclear leukocytes In man such involvement is thought to heal without permanent damage Chronic interstitial nephritis in which similar pathology has progressed to degeneration and atrophy and fibrosis of renal tissue may also be seen Such lesions may follow the chronic infiltration with leukemia cells or the cells of multiple myeloma

The kidneys and renal pelves may be involved by suppurative processes as the result of (1) organisms reaching the interstitial tissues by way of the blood stream or (2) ascending infection from the lower urinary tract either by way of the ureters themselves or of the periureteral lymphatics When the kidney alone is involved by blood borne infections the condition of *focal* or *embolic* suppurative interstitial nephritis obtains This is frequently the result of staphylococcal infection blood borne from suppurative processes elsewhere in the body In bacterial endocarditis septic emboli to the kidney may result in a focal process which is frequently also accompanied by changes resembling those of acute glomerulonephritis Occasionally colon bacilli are found although the colon bacillus appears to be a rare causative agent in this type of nephritis Microscopically multiple small purulent foci are seen which may coalesce to form a larger *renal carbuncle* Occasionally the spread of such an infection to the perinephric tissues results in the formation of a perinephric abscess Here local tenderness or swelling in the costovertebral angle with pain on motion of the trunk (evidence of psoas muscle irritation) may give a clue to the diagnosis

A syndrome has been described following deep radiation to the renal areas which resembles those of acute nephritis and may progress to a picture similar to the chronic stage Changes begin 6 to 12 months after cessation of therapy with proteinuria but no hematuria There are a few such cases that go on to hypertension and azotemia and die in uremia Microscopically one notes a generalized intertubular fibrosis and in the later stages hyaline obliteration of the glomeruli with fibrinoid necrotic lesions of arterioles

VASCULAR NEPHRITIS

The term *vascular nephritis* includes several disorders in which the prime etiologic factor is disease of the renal vasculature This in turn usually reflects disease of the systemic vessels

Nephrosclerosis

The characteristic lesion of renal vascular disease is sclerosis of the arterioles manifested particularly by hyaline thickening of the intima of the afferent arteriole of the glomerulus This may be seen in other types of renal disease Indeed its end result —the scarred contracted kidney—is extremely difficult to differentiate from the final stage of chronic pyelonephritis or glomerulonephritis In the benign or slowly progressive form of "essential hypertension this intimal thickening results in sclerosis of the arterioles and the resultant narrowing of the lumen compromises the blood supply to the areas supplied This leads to a patchy fibrosis with areas of normal tissue between Characteristically one sees a spotty thickening of the basement membrane of the glomerulus and finally obliteration of the capillary tuft Further tubular destruction and fibrosis result with renal function compromised according to the extent of the damage The end result of the fibrous changes is a contracted scarred kidney These renal vascular changes however do not necessarily reflect vascular changes elsewhere in the body In the malignant phase of essential hypertension the characteristic changes are a rapidly progressing endarteritis obliterans with marked thickening (onionskin) of the intima of the arterioles and necrosis of both the media and the intima If the onset is sudden and the progress rapid enough death may ensue before the fibrotic changes decrease the size of the kidney The pathologist then sees a normal sized kidney with the microscopic changes previously described and with its surface in the gross studded with punctate hemorrhages which resemble the embolic flea bitten

saturated urinary salts is an important etiologic concept Of recent interest is the fact that drugs tending to decrease urinary citrate excretion such as Diamox may play a role in the etiology of renal calcium calculi Hypercalcuria with or without hypercalcemia is an all important factor and must be carefully investigated The common causes for hypercalcuria are prolonged bed rest particularly in the postmenopausal stage metastatic bone tumors multiple myeloma Cushing s disease sarcoidosis vitamin D intoxication excess intake of calcium and phosphate (particularly as dairy products) hyperparathyroidism (5 per cent of urinary calculi are associated with parathyroid disease) acidosis and idiopathic hypercalcuria The latter condition appears predominantly in male patients The serum calcium and phosphate are normal

Diagnosis Patients with renal calculi may not infrequently be asymptomatic Renal calculi should be looked for in any of the above disease states Occasionally hematuria alone will be a manifestation Classically the passage of a renal stone down the ureter results in severe colicky pain radiating to the groin flank and testis and accompanied by the passage of clots and gross or microscopic blood Large staghorn" calculi may be asymptomatic except for vague costovertebral angle pain and the symptoms of obstruction and infection of the kidney The calcium containing stones and the mixed stones are radiopaque as is the cystine stone Uric acid stones are not The latter do not necessarily occur in patients with clinical gout and appear to be more frequent in patients of Jewish and Italian origins Evidence of osteomalacia or osteoporosis by x ray should lead to investigation for renal calculi In patients with normal renal function the Sulkowitch test performed on a casual urine specimen may indicate hypercalcuria This however should be checked by analysis of 24 hour urine specimens after several days of a 200 mg calcium diet Cystinuria may be indicated by the nitroprusside test but paper chromatography is perhaps essential Crystals of uric acid phosphate and cystine may be identified in dried urine specimens but with the exception of the latter they may not necessarily have significance for the etiology of the renal calculus The pH of a fresh urine specimen may give some clue as to the etiology of the stone since characteristically uric acid stones occur in acid urine and the mixed calcium stones in alkaline urines Where it can be obtained of course crystallographic analysis of the stone itself is conclusive and occasionally such a technique may reveal the presence of an artefactual inclusion of a psychoneurotic or malingerer

Therapy The general principles of the treatment of renal calculi are to treat the underlying disease particularly that causing hypercalcuria It is important to eliminate stasis and infection by appropriate means The urine volume should be maintained high to decrease the concentration of precipitable materials The injection of hyaluronidase to increase the excretion of urinary protective colloids which may decrease the formation of concretions has been advocated The use of this substance is of questionable value The ingestion of substances such as aspirin which are conjugated as glucuronides and excreted as such is apparently of some value Glucuronides significantly increase the solubility of calcium phosphate

In addition to the general measures patients with calcium stones should be placed on a diet low in calcium and phosphate The ingestion of aluminum hydroxide gels decreases the excretion of phosphate although it may result in an initial increase in calcium excretion Immobilized patients should receive physiotherapy to decrease mobilization of calcium from bony structures The use of mild acidifying agents to maintain a low urinary pH is of value However systemic acidosis may increase calcium mobilization if therapy is too vigorous There is no evidence that ingestion of foods high in oxalate increases the incidence of calcium oxalate stones Magnesium ammonium phosphate stones (triple phosphate) should be treated with mild acidifying agents aluminum hydroxide gels and appropriate antibiotics to discourage urea splitting infections Possibly a low protein diet to decrease urinary urea may be of value If there is no other contraindication patients with uric acid and cystine stones should be treated with mild alkali (sodium citrate) to increase the solubility of these substances in the urine

TUMORS OF THE KIDNEY AND BLADDER

With the exception of benign cysts and a rare large adenoma tumors of the kidney must be regarded as malignant Because of the late appearance of symptoms and signs of sufficient magnitude to lead to investigation and accurate detection the mortality in this disease is high Renal cell carcinoma is the most frequent tumor of the kidney appearing predominantly in the fourth to the seventh decade Early invasion of the small veins and the renal vein gives rise to metastatic spread to the liver lungs and bone Occasionally invasion of the left renal vein with obstruction of the spermatic vein may result in a varicocele Renal cell carcinomas may produce alkaline phosphatase so that the serum concentration may be elevated enough to be of diagnostic importance In children embryomas of the kidney are of importance These tumors are relatively undifferentiated and metastasize early by way of the small blood vessels Papillary carcinomas of the transitional epithelium of the

the adequacy of adaptive mechanisms in the face of very slowly progressing uremia There is nothing characteristic about the urinary findings except intermittent bouts of hematuria which may occasionally lead to massive hemorrhages into these cysts Typically large firm lobulated masses are palpable in the flanks Before the onset of renal failure the intravenous pyelogram may give a characteristic picture Surgical puncture and drainage of the cyst results in temporary relief of pressure phenomena but is of little long term benefit The treatment is that of the resulting hypertensive disease and uremia and of the frequent infection

Unilateral Renal Agenesis This is found in about 0 1 per cent of routine autopsies It is more frequent in males the left kidney is more frequently absent with hypertrophy of the opposite kidney which may be involved in an abnormality predisposing to pyelonephritis Possible absence of the contralateral kidney should always be considered when advocating unilateral nephrectomy *Hypogenesis* of one kidney is slightly more frequent and may result in a small functionless kidney frequently with pyelonephritic change The joining of two kidneys by a fibrous band or a band of renal tissue (*horseshoe kidney*) occurs occasionally and is without clinical significance except for the predisposition to pyelonephritis Duplication of the ureters or a double renal pelvis is of clinical importance only for the same reason Aberrant renal vessels rarely cause difficulty unless they cause obstruction to the urinary outflow tract or to the renal blood supply A congenitally *ectopic kidney* may be present in the true pelvis or in the iliac fossa connected to the bladder by an extremely short ureter It may give little difficulty except during pregnancy although again such abnormalities predispose to retrograde infection *Abnormal mobility of the kidney* may result in *nephroptosis* The ureter is of normal length although the kidney itself may be found just above the pelvis Congenital defects in body habitus lack of normal renal supporting structures postural defects and the stress of constant muscular straining or coughing may all contribute to nephroptosis Frequently there are no symptoms and those which do occur are usually due to interference with drainage of the ureter or to the blood supply giving rise to colicky pain (*Dietl's crisis*) Therapy is directed at supporting the organ externally and correcting the postural defects Surgical procedures are indicated only when it can be proved that the symptoms are the result of the malposition of the kidney

METABOLIC RENAL DISORDERS

Generalized Renal Calcinosis This may occur with or without stone formation is the result of disturbances of calcium and phosphorus metabolism (Chap 74) Among the specific etiologic factors are hyperparathyroidism hypervitaminosis D and excess calcium and/or alkali ingestion particularly in the presence of previous pyelonephritis These changes may progress to renal failure and death and the recognition of these conditions is important because at least in the early stages they are potentially reversible by appropriate therapy High serum calcium levels in uremia should lead the physician to investigate one of the above possibilities or alternatively those of myeloma kidney or sarcoidosis

The renal lesion and impairment of function arise from deposition of calcium in the renal interstitium with resultant fibrosis Occasionally renal calcinosis may be revealed by x ray although marked impairment may exist without x ray evidence of calcification Indeed it is probable that factors other than calcium deposition per se are operative The presence of band keratopathy is confirmatory evidence of hypercalcemia of long standing and its presence in renal failure suggests primary metabolic disease rather than hyperparathyroidism secondary to renal failure Renal disease secondary to systemic sarcoidosis results not only from involvement of the kidney by the granulomata but also by lesions similar to those of hypervitaminosis D Adrenal steroid therapy may result in some improvement Renal calculi have been seen in sarcoidosis

Gouty nephritis with renal failure may result from the interstitial deposition of urate crystals and patchy fibrosis The effect in diminishing such deposits by the long term use of uricosuric agents has not been properly evaluated The vascular component in gouty nephritis bears equal weight with the interstitial element

Myxedema This may be accompanied by abnormalities of renal dynamics and diminution of tubular maximal excretory and resorptive capacity Inborn errors of metabolism localized in the renal tubule and elsewhere may give rise to abnormal urinary constituents which in some instances may be reflected by disturbances of body fluid constituents These are discussed in more detail in Chaps 48 and 49

Diagnosis and Treatment of Nephrolithiasis A discussion of the mechanism of stone formation has been given in Chap 19 Of the clinically important types of renal calculi calcium phosphate stones comprise approximately 51 per cent calcium oxalate 13 per cent magnesium ammonium phosphate 20 per cent cystine 1 per cent and uric acid 6 per cent It should be remembered that frequently these stones are mixed The role of urinary tract infection and stasis cannot be too strongly stressed as an etiologic agent in stone formation The presence of a nidus for the precipitation of the super-

cortical necrosis In this latter syndrome the afferent arteriole and glomeruli may be involved as well In the experimental production of these lesions and in the pathologic picture there is evidence for the operation of a shunt of blood from the cortex through the medulla by way of the juxtamedullary glomeruli as suggested by earlier work Since however severe specific nephrotoxic insults are usually accompanied by circulatory disturbances the lesion here may be mixed and the common denominator may be ischemia Interstitial edema and loss of the tubular basement membrane were seen in both types of lesions The random regeneration of proliferating epithelial sheets as well as the persistent disruption of the tubular wall suggests that function in the nephrons may be permanently destroyed Although recurrent intravascular hemolysis with hemoglobinuria has been proved to cause a diffuse fibrotic process in the kidneys the relation of the heme pigment cast per se to the tubular damage is put in doubt by the lack of relation between tubular damage and the proximity of the pigment cast

Differential Diagnosis The first question to be asked by the physician confronted by acute renal failure is Is the process immediately reversible? (Chap 231) One must consider the possibility of obstruction of shock and severe dehydration On the other hand poorly documented chronic disease may frequently present as acute renal failure Here the size of the kidneys by x ray may be a valuable differential point A plain film of the abdomen (not an intravenous pyelogram) should be made Occasionally bilateral emboli to the renal vessels may be involved Renal failure resulting from circulatory disturbances or disorders of fluid balance have been termed *prerenal* or *extrarenal* uremia The dividing line between prerenal disturbances and intrinsic renal disease is not clear-cut however and the former if prolonged may result in diffuse parenchymal lesions

Clinical Course The primary manifestation of acute renal failure is suppression of the urine volume Less acute processes may occasionally impair the ability to excrete solutes without markedly decreasing volume but this is rare The duration of suppression may be a matter of 24 hr or as long as 6 weeks after which urine volume may increase Intermittent oliguria and polyuria strongly suggest obstructive uropathy not disease of the renal parenchyma

Oliguric Phase Total anuria for periods of more than 2 to 3 days is rare in acute renal failure When it does occur one should suspect acute glomerulonephritis or obstruction of the urinary tract More common is severe oliguria of 20 to 200 ml per day If the urine is poorly concentrated and there is a large load of metabolite to be excreted 400 to 500 ml per day may also represent acute renal failure The urine may be grossly bloody during the first few days of oliguria and show a typical dark red or brown color if hemolysis has occurred Proteinuria may be marked in the beginning and tends to clear After the first 2 days the urine specific gravity drops to 1 010 or below Small numbers of granular casts or heme pigment casts are seen as the oliguria continues Decreasing numbers of erythrocytes and increasing pyuria are seen although hematuria may persist as a result of irritation from a urethral catheter If acute renal failure has been precipitated by an acute traumatic episode as is frequently the case the serum nonprotein nitrogen mounts rapidly at first and less rapidly as oliguria continues This is markedly influenced by factors affecting protein catabolism Serum sodium and chloride concentrations tend to drop blood bicarbonate decreases as acid metabolites accumulate Serum potassium may be elevated and occasionally this rise is acute and marked Serum calcium tends to be depressed All of these values are markedly modified by the form of therapy and the factors increasing the catabolism of protein A normochromic and normocytic anemia frequently becomes manifest and the blood leukocyte count may rise as high as 25 000 even in the absence of obvious infection With progressive nitrogen retention nausea and vomiting appear marked abdominal distention may be troublesome and in prolonged oliguria diarrhea occasionally with bloody stools may occur The neuromuscular symptoms are those previously described for the general picture of uremia (p 161) and include somnolence disorientation twitching and convulsions Elevation of the diastolic blood pressure (100 mm Hg or more) occurs in 65 per cent of the cases and may be severe Retinal changes are infrequent although marked alterations including separation of the retina have been seen in acute renal failure accompanying eclampsia Congestive heart failure and acute pulmonary edema are dreaded and not infrequent complications the incidence depending to some extent upon the severity of the hypertension and the zeal with which fluid is administered Occasionally one sees acute heart failure not related to these factors which appears to be accompanied by a high cardiac output and may be related to the uremia itself Acute spontaneous potassium intoxication is a completely reversible complication which with adequate treatment is becoming less frequent Formerly it was a common cause of death High extracellular levels of potassium and more important a high extracellular intracellular ratio of potassium result from the catabolism of potassiu containing tissue and from the effect of uremia acidosis on the distribution of this ion n cell membrane This may r t upon the neuromuscular syst

pelvis and ureter may occur metastasizing locally and occasionally by the hematogenous route Epidermoid carcinoma of the renal pelvis may follow long standing chronic infection and renal calculi This tumor spreads by local extension and invasion of the lymphatics Morphologically over 90 per cent of tumors of the bladder are papillary All of these tumors are potentially malignant and require the evaluation of a skilled urologist and pathologist A small percentage arises *from metaplasia of the* bladder epithelium following long standing cystitis They occur most commonly after the fifth decade and males are predominantly affected Whether tumors are benign or malignant their interference with ureteral drainage or emptying of the bladder may result in infection or obstruction or both This *complication is a more common cause of death than* metastasis of the tumor

The most common and important sign both of tumors of the kidney and of the bladder is painless asymptomatic hematuria This may be microscopic gross or intermittent Its appearance particularly in the absence of proteinuria and cylindruria *requires rapid and thorough investigation of the entire* genitourinary tract Patients with tumors of the kidney may complain of vague pain or gastrointestinal symptoms as well as questionable fullness in the flank and upper abdomen Occasionally the passage of blood clots down the ureter may give colicky pain Specific symptoms however occur *relatively late in the disease and spontaneous pain*less bleeding is of the utmost importance The diagnosis is made by cystoscopy or by excretory urography or retrograde pyelography when indicated Cytologic examination of the urine for malignant cells may be an adjunct Arteriography may furnish valuable evidence in selected cases when the findings by pyelography are not definite The treatment for kidney tumors and tumors of the bladder is surgical

The kidneys are involved in the lesion of Hodgkin s disease in about 25 per cent of the cases but rarely is the involvement severe enough to yield renal failure unless pyelonephritis is superimposed

ACUTE RENAL FAILURE

The term acute renal failure implies sudden and *virtually complete failure of excretory function* This may be due to the rapid onset or progression of renal diseases already discussed e g acute glomerulonephritis malignant hypertension or fulminating pyelonephritis More frequently the phrase connotes an acute circulatory or toxic insult to previously normal kidneys resulting in sudden renal failure which is potentially largely reversible

Etiology The causes of acute renal failure are varied Specific toxins such as bichloride of mercury carbon tetrachloride diethyleneglycol and mushroom ingestion may be implicated Nonspecific *substances such as large amounts of sucrose* and the sulfonamides may be at fault In the latter instance either a specific sensitivity involving the kidneys in a vascular lesion or precipitation of insoluble sulfonamide compounds in the renal tubules may be causative During two world wars the syndrome has been recognized as attributable to cir*culatory disturbances such as profound* shock crushing injuries and other severe traumas It may follow severe hypotension occurring with myocardial infarction Incompatible blood transfusion and intravascular hemolysis from other causes (black water fever) may precipitate acute renal failure Among the infectious diseases responsible are *Weil s disease and hemorrhagic fever Bilateral* symmetric cortical necrosis of the kidney may be seen during the course of pregnancy—particularly but not necessarily when complicated by toxemias It may also occur in both sexes following severe hypotension Severe depletion of water and electrolytes presumably operating through circulatory *mechanisms may also result in acute renal failure* The conventional histologic sections of kidneys from patients who died with renal injury as a result of incompatible transfusions shock and crushing injuries indicated that the necrotic lesion was limited to the distal tubule The term *lower nephron nephrosis* was therefore coined for this pathologic entity *More recently workers studying* whole nephrons teased out and reconstructed from similar cases have found that the lesion is not limited to the distal tubule and it appears that acute tubular necrosis is to be preferred to the previous nomenclature Two types of lesions are described in these studies

1 A nephrotoxic necrosis caused by specific toxins in which the lesion is limited to the proximal tubules which are functionally concerned with the resorptive handling of the filtered toxins The lesion here is necrosis *of the epithelial cell with desqua*mation and disintegration of the tubular epithelium The cellular lumen may be filled with nuclear debris and cellular detritus All nephrons are equally involved since the distribution of the toxin is by way of the bood stream

2 The second characteristic lesion is disruption *of the integrity* of the renal tubule (tubulorhexis) with actual leakage of tubule contents into the interstitium These lesions are scattered among the nephron and may appear in any part thereof Ischemia is thought *to be responsible for* the production of this random damage since ischemia regularly produces irregular and spotty distribution of blood flow through the cortex Such damage may be seen at its maximum in the intermittent ing of the wedge shaped areas of infar

cortical necrosis In this latter syndrome the afferent arteriole and glomeruli may be involved as well In the experimental production of these lesions and in the pathologic picture there is evidence for the operation of a shunt of blood from the cortex through the medulla by way of the juxtamedullary glomeruli as suggested by earlier work Since however severe specific nephrotoxic insults are usually accompanied by circulatory disturbances the lesion here may be mixed and the common denominator may be ischemia Interstitial edema and loss of the tubular basement membrane were seen in both types of lesions The random regeneration of proliferating epithelial sheets as well as the persistent disruption of the tubular wall suggests that function in the nephrons may be permanently destroyed Although recurrent intravascular hemolysis with hemoglobinuria has been proved to cause a diffuse fibrotic process in the kidneys the relation of the heme pigment cast per se to the tubular damage is put in doubt by the lack of relation between tubular damage and the proximity of the pigment cast

Differential Diagnosis The first question to be asked by the physician confronted by acute renal failure is Is the process immediately reversible? (Chap 231) One must consider the possibility of obstruction of shock and severe dehydration On the other hand poorly documented chronic disease may frequently present as acute renal failure Here the size of the kidneys by x ray may be a valuable differential point A plain film of the abdomen (not an intravenous pyelogram) should be made Occasionally bilateral emboli to the renal vessels may be involved Renal failure resulting from circulatory disturbances or disorders of fluid balance have been termed *prerenal* or *extrarenal* uremia The dividing line between prerenal disturbances and intrinsic renal disease is not clear cut however and the former if prolonged may result in diffuse parenchymal lesions

Clinical Course The primary manifestation of acute renal failure is suppression of the urine volume Less acute processes may occasionally impair the ability to excrete solutes without markedly decreasing volume but this is rare The duration of suppression may be a matter of 24 hr or as long as 6 weeks after which urine volume may increase Intermittent oliguria and polyuria strongly suggest obstructive uropathy not disease of the renal parenchyma

Oliguric Phase Total anuria for periods of more than 2 to 3 days is rare in acute renal failure When it does occur one should suspect acute glomerulonephritis or obstruction of the urinary tract More common is severe oliguria of 20 to 200 ml per day If the urine is poorly concentrated and there is a large load of metabolite to be excreted 400 to 500 ml per day may also represent acute renal failure The urine may be grossly bloody during the first few days of oliguria and show a typical dark red or brown color if hemolysis has occurred Proteinuria may be marked in the beginning and tends to clear After the first 2 days the urine specific gravity drops to 1 010 or below Small numbers of granular casts or heme pigment casts are seen as the oliguria continues Decreasing numbers of erythrocytes and increasing pyuria are seen although hematuria may persist as a result of irritation from a urethral catheter If acute renal failure has been precipitated by an acute traumatic episode as is frequently the case the serum nonprotein nitrogen mounts rapidly at first and less rapidly as oliguria continues This is markedly influenced by factors affecting protein catabolism Serum sodium and chloride concentrations tend to drop blood bicarbonate decreases as acid metabolites accumulate Serum potassium may be elevated and occasionally this rise is acute and marked Serum calcium tends to be depressed All of these values are markedly modified by the form of therapy and the factors increasing the catabolism of protein A normochromic and normocytic anemia frequently becomes manifest and the blood leukocyte count may rise as high as 25 000 even in the absence of obvious infection With progressive nitrogen retention nausea and vomiting appear marked abdominal distention may be troublesome and in prolonged oliguria diarrhea occasionally with bloody stools may occur The neuromuscular symptoms are those previously described for the general picture of uremia (p 161) and include somnolence disorientation twitching and convulsions Elevation of the diastolic blood pressure (100 mm Hg or more) occurs in 65 per cent of the cases and may be severe Retinal changes are infrequent although marked alterations including separation of the retina have been seen in acute renal failure accompanying eclampsia Congestive heart failure and acute pulmonary edema are dreaded and not infrequent complications the incidence depending to some extent upon the severity of the hypertension and the zeal with which fluid is administered Occasionally one sees acute heart failure not related to these factors which appears to be accompanied by a high cardiac output and may be related to the uremia itself Acute spontaneous potassium intoxication is a completely reversible complication which with adequate treatment is becoming less frequent Formerly it was a common cause of death High extracellular levels of potassium and more important a high extracellular intracellular ratio of potassium result from the catabolism of potassium containing tissue and from the effect of uremia and acidosis on the distribution of this ion across the cell membrane This may result in striking effects upon the neuromuscular system manifested by de

pelvis and ureter may occur metastasizing locally and occasionally by the hematogenous route Epidermoid carcinoma of the renal pelvis may follow long standing chronic infection and renal calculi This tumor spreads by local extension and invasion of the lymphatics Morphologically over 90 per cent of tumors of the bladder are papillary All of these tumors are potentially malignant and require the evaluation of a skilled urologist and pathologist A small percentage arises from metaplasia of the bladder epithelium following long standing cystitis They occur most commonly after the fifth decade and males are predominantly affected Whether tumors are benign or malignant their interference with ureteral drainage or emptying of the bladder may result in infection or obstruction or both This complication is a more common cause of death than metastasis of the tumor

ACUTE RENAL FAILURE

The term acute renal failure implies sudden and virtually complete failure of excretory function This may be due to the rapid onset or progression of renal diseases already discussed e g acute glomerulonephritis malignant hypertension or fulminating pyelonephritis More frequently the phrase connotes an acute circulatory or toxic insult to previously normal kidneys resulting in sudden renal failure which is potentially largely reversible

Etiology The causes of acute renal failure are varied Specific toxins such as bichloride of mercury carbon tetrachloride diethyleneglycol and *mushroom ingestion* may be implicated Nonspecific substances such as large amounts of sucrose and the sulfonamides may be at fault In the latter instance either a specific sensitivity involving the kidneys in a vascular lesion or precipitation of insoluble sulfonamide compounds *in the renal tubules* may be causative During two world wars the syndrome has been recognized as attributable to circulatory disturbances such as profound shock crushing injuries and other severe traumas It may follow severe hypotension occurring with myocardial infarction Incompatible blood transfusion and intravascular hemolysis from other causes (blackwater fever) may precipitate acute renal failure Among the infectious diseases responsible are Weil s disease and hemorrhagic fever Bilateral symmetric cortical necrosis of the kidney may be seen during the course of pregnancy—particularly but not necessarily when complicated by toxemias It may also occur in both sexes following severe hypotension Severe depletion of water and electrolytes presumably operating through circulatory mechanisms may also result in acute renal failure The conventional histologic sections of kidneys from patients who died with renal injury as a result of incompatible transfusions shock and crushing injuries indicated that the necrotic lesion was limited to the distal tubule The term *lower nephron nephrosis* was therefore coined for this pathologic entity More recently workers studying whole nephrons teased out and reconstructed from similar cases have found that the lesion is not limited to the distal tubule and it appears that acute tubular necrosis is to be preferred to the previous nomenclature Two types of lesions are described in these studies

1 A nephrotoxic necrosis caused by specific toxins in which the lesion is limited to the proximal tubules which are functionally concerned with the resorptive handling of the filtered toxins The lesion here is necrosis of the epithelial cell with desquamation and disintegration of the tubular epithelium The cellular lumen may be filled with nuclear debris and cellular detritus All nephrons are equally involved since the distribution of the toxin is by way of the bood stream

2 The second characteristic lesion is disruption of the integrity of the renal tubule (tubulorhexis) with actual leakage of tubule contents into the interstitium These lesions are scattered among the nephron and may appear in any part thereof Ischemia is thought to be responsible for the production of this random damage since ischemia regularly produces irregular and spotty distribution of blood flow through the cortex. Such damage may be seen at its maximum in the intermittent scattering of the wedge

syndrome The therapeutic approach must first concern itself with the search for reversibility in the underlying disease process Failing this the therapist must realize that overtreatment may be more dangerous than intelligent neglect To attempt to maintain a normal chemical pattern in the face of advanced renal failure is to neglect the obvious possibility that a normal serum bicarbonate concentration for example may not be "normal for the patient with marked retention of acid metabolites that in the latter instance it is in effect a compensatory mechanism by which the more important factor of pH is stabilized The enthusiastic therapist is not infrequently surprised at the improvements which result when in discouragement he has abandoned attempts to force diuresis correct acidosis and maintain normal hemoglobin levels by transfusion

Treatment of Acute Renal Failure The first principle of the treatment of acute renal failure is to correct if possible the underlying defect This includes correction of hypotension the restoration of fluid and electrolyte losses and the appropriate therapy for obstruction A seriously dehydrated patient may have already sustained a tubular lesion in which case no amount of saline or blood will result in diuresis and indeed supplying these fluids may lead to overhydration which may produce circulatory embarrassment at a later date In spite of this possibility replacement therapy must always be given when clinically indicated but given cautiously As previously mentioned the deposition of heme pigment casts in the tubules is not the prime factor in the tubular lesions Therefore the use of intravenous alkali following intravascular hemolysis (e g with incompatible transfusion) in an attempt to increase hematin solubility must be reevaluated In any case if the renal tubules can alkalinize the urine in response to bicarbonate or lactate infusion no more than 5 Gm is necessary More than this does not increase the probability of prevention of heme damage and may greatly aggravate the problem if the renal lesion is such that the sodium cannot be excreted For a specific heavy metal intoxication such as mercury intoxication BAL should be administered although by the time the renal lesion has occurred the efficacy of BAL may be minimal Decapsulation of the kidney spinal anesthesia and intravenous procaine have no proved therapeutic value in the treatment of acute renal failure Lavage of the renal pelvis with warm bicarbonate solution may be attempted for sulfonamide concretions but otherwise has little value Cortisone and ACTH therapy to prevent inflammatory response and renal edema has been tried but without success

Once it is apparent that the renal lesion has occurred and severe oliguria supervenes the problem then becomes one of maintaining the patient in the optimal state until spontaneous healing and diuresis take place A first consideration is that of *caloric requirements* Since it is the products of protein catabolism which in large part give rise to the toxic metabolites that accumulate in renal failure to minimize protein catabolism becomes a prime aim of therapy The protein sparing effects of the administration of glucose and fructose are well known Emulsions of fat which have an even higher caloric value per unit weight have been advocated Since however acute renal failure tends to be a self limited disease usually occurring in well nourished individuals with adequate stores of body fat it would seem wise to permit them to burn endogenous fat rather than to force upon them the fatty emulsions which may well aggravate nausea vomiting and diarrhea with resultant electrolyte losses—effects that in themselves present more serious problems In the author s experience it has been a satisfactory method of treatment to administer glucose solutions alone This is best accomplished by the use of a 50 per cent solution of glucose and water administered in a slow constant drip by means of a plastic catheter placed in one of the larger veins by insertion and threading through the saphenous vein or an antecubital vein after introduction through a No 13 needle This location in a large vessel minimizes venous irritation and the thrombosis which may result. The catheter should be shifted from one side to the opposite side every 6 days to diminish the risk of infection and thrombosis Its placement through an arm vein is to be preferred because the possibility of thrombophlebitis and embolism is greater from the lower limb veins For patients suffering from nausea and vomiting all oral intake should be kept to minimum although occasionally small amounts of buttered toast and sweet tea may be tolerated

After correction of existing losses *fluid* should be limited to replacement amounts only The total volume should be calculated from amounts lost by way of the gastrointestinal tract, plus an insensible loss of 0 5 ml/kg body weight/hr with increments for fever and for obvious sweating Insensible losses may be greatly increased by activity and the basal losses per kg body weight are much greater in children than in adults Recent evidence that endogenous water production from fat catabolism may be greater than previously estimated may necessitate keeping the figure for fluid replacement even lower than calculated on this basis When only 300 ml of fluid per day is indicated the provision of the minimal glucose requirements (150 Gm per day for the adult) in this amount necessitates its administration by the method described Wherever possible daily weights should be checked since it is obvious that if inadequate calories are provided

pression and finally loss of deep tendon reflexes and progressing to complete paralysis The cause of death is the resulting disturbance in the conducting system of the heart which may give rise to ventricular arrhythmias and death Electrocardiographic changes are characteristic and pass through a typical sequence beginning early with high pointed T waves in the precordial leads and a spread of the QRS complex with depression of the P waves in the standard leads and a sloping S T segment These changes may progress until the complexes resemble a sine wave at which time ventricular fibrillation may result as the terminal episode

Diuretic Phase Diuresis may begin at any time up to 6 weeks Rarely the urine volume may increase rapidly progressing from 20 to 30 ml per day to 2 500 ml within a 24 hr period Such rapid increases suggest renal vascular spasm as an etiologic factor in the oliguria More characteristic however is a stepwise increase in volume with increments of 200 to 300 ml per day An occasional patient may reach a plateau at 500 to 600 ml per day which persists for a week or more It is possible in these instances that a few nephrons capable of producing such a volume recover more rapidly than the bulk of the nephron population It is important to keep in mind that less than a liter of poorly concentrated urine particularly in the presence of infection and resorption of blood or necrotic tissue is frequently totally inadequate for amelioration of uremia The large urinary losses of sodium chloride and water which may occur during the diuretic phase have been stressed In patients who have been overhydrated however or in whom the metabolic production of water has been excessive such a diuresis may represent only loss of excess extracellular fluid and the accompanying weight loss may be beneficial In others true negative balance may result necessitating replacement Potassium losses also may be excessive Early in the diuretic phase one may see a continued rise of nonprotein nitrogen and even potassium in spite of urinary volumes of over 3 l per day A series of patients has been described in whom marked retention of sodium hypernatremia and central nervous system signs occur during the diuresis following anuria A frequent complication of the diuretic phase may be renal infection as evidenced by pyuria with or without clinical signs of pyelonephritis Otherwise the blood chemical picture usually returns to normal gradually renal function tests improve although a mild anemia and an inability to concentrate the urine may persist for some months

Prognosis In the uncomplicated case the prognosis is good if the patient is well managed Causes of death during the oliguric phase are congestive heart failure acute pulmonary edema convulsions potassium intoxication and more usually sequelae of the concomitant trauma which precipitated the acute renal failure The more sensitive tests of renal function may indicate permanent impairment following an acute episode although there may be no nitrogen retention or other chemical evidence of renal failure Unlike the changes of pyelonephritis or glomerulonephritis these changes do not appear to be progressive

CHRONIC RENAL FAILURE

The clinical picture of chronic renal failure is largely that of the associated hypertension and uremia which has been discussed in Chaps 20 and 227 The progression varies somewhat with the etiology Thus renal failure due to polycystic disease and nephrocalcinosis may run a slower and more benign course than that of chronic glomerular nephritis possibly because of the slower tempo of nephron destruction In general however the degree and rapidity of destruction of renal tissue and the magnitude of the associated hypertension determine the course which may be modified (but not reversed) by judicious treatment

Treatment of Renal Failure

By the term renal failure we imply inability of the kidneys to excrete the daily metabolic waste load presented for elimination The result of this is the retention of organic and inorganic metabolites which when marked gives rise to the clinical syndrome of uremia Regardless of our inability to explain it precisely these chemical abnormalities are responsible for the clinical signs and symptoms In general it is true that this is a chemical problem with which we have to deal and in the advanced stages it is independent of the type of renal disease which originates it The exception to this statement is the fact that some types of renal disease are more frequently accompanied by infection hypertension and more rapid progression which will then influence the clinical picture The correlation of any specific type of renal disease with these latter factors however is never so precise that it constitutes a real point in diagnosis and prognosis From the point of view of therapy as well as of prognosis we may well divide renal failure into the acute and chronic problems These differ by reason of the remarkable ability of the human organism to adapt to even marked chemical abnormalities if time for compensation is allowed Into this pattern too is woven the nutritional status and the adrenal activity of the acute and chronic patient In acute renal failure the causative agent may frequently be a therapeutic problem e g shock and the crush

After correction of existing losses *fluid* should be limited to replacement amounts only The total volume should be calculated from amounts lost by way of the gastrointestinal tract plus an insensible loss of 0 5 ml/kg body weight/hr with increments for fever and for obvious sweating Insensible losses may be greatly increased by activity and the basal losses per kg body weight are much greater in children than in adults Recent evidence that endogenous water production from fat catabolism may be greater than previously estimated may necessitate keeping the figure for fluid replacement even lower than calculated on this basis When only 300 ml of fluid per day is indicated the provision of the minimal glucose requirements (150 Gm per day for the adult) in this amount necessitates *its admin*istration by the method described Wherever possible daily weights should be checked since it is obvious that if inadequate *calories are provided*

and the patient does not lose weight too much fluid has been given

Electrolyte requirements necessitate that the intake be potassium free since potassium intoxication is a potential hazard Chloride and sodium losses in the gastrointestinal tract should be replaced as indicated in view of the fact that more chloride is lost from gastric juice and more sodium from losses below the pylorus An increment of less than 1 Gm of sodium chloride for insensible loss may be added although this may be considerably larger in frank sweating In the author s view depression of serum sodium levels is not an indication for sodium therapy unless it can be proved that such levels are due to excess sodium loss Alternative explanations not requiring replacement therapy are intracellular movement of sodium metabolic readjustment of body fluid tonicity and dilution of concentrations by excess water production or administration The last is best treated by drastic water restriction as outlined above Infection should be vigorously treated since it results in increased protein catabolism The fact that there is no renal mechanism for the excretion of the chemotherapeutic agent chosen should be kept in mind In all cases adequate vitamin supplements should be given The administration of testosterone proprionate 50 mg a day may have value because of its anabolic effect *Congestive heart failure* must be treated in the usual manner (Chap 226) Improper fluid administration frequently precipitates this situation and it may be improved by restricting the fluid intake In many instances digitalis seems less effective than in congestive heart failure uncomplicated by uremia Because of the increased danger of arrythmias in uremic patients digitalis preparations should never be given intravenously The wisdom of treating mild to moderate degrees of *anemia* in the anuric patient by whole blood transfusion is in grave doubt In the author s view a hematocrit of 30 or less is the only indication for therapy which then should consist of small repeated transfusions of freshly drawn packed red blood cells

The hazard of *potassium intoxication* may be reduced by the use of cation exchange resin enemata Impaction of the material in the large bowel and the removal of sodium on the resin are problems to be considered Advanced degrees of potassium intoxication may be treated by hypertonic sodium bicarbonate sodium chloride and calcium gluconate and perhaps more effectively by the infusion of hypertonic glucose and insulin Where immediate treatment is necessary the sodium salts whose action is apparent in a matter of minutes should be used This consideration must be weighed against the potential hazard of giving a sodium load to an anuric patient The removal of potassium from the blood by use of the various forms of dialysis is more effective and of greater duration and may be employed when life is threatened For the symptomatic treatment of restlessness and convulsions rectal or intramuscular paraldehyde has been widely used magnesium sulfate intramuscularly (as discussed in Chap 227) may be more specific for the central nervous system manifestations Barbiturates if used should be of the variety metabolized by the liver (Seconal and Amytal) rather than those excreted by the renal pathway (phenobarbital barbital) Results with Promazine (Sparine) have apparently been extremely favorable During the *diuretic phase* the replacement of sodium and water losses should be influenced by the considerations mentioned previously Under these circumstances hyponatremia is a more valid indication for hypertonic sodium therapy The clinical response to such infusions may guide further therapy An occasional patient may retain sodium during the diuretic phase with a resultant marked hypernatremia and hyperchloremia This syndrome is frequently associated with central nervous system disturbances and a low urinary pH During the diuretic phase with volumes of urine greater than 1 500 ml per day dietary management need be less severe Under these circumstances the patient may be allowed by mouth anything which he desires and will tolerate It must be remembered however that urine volumes of less than 1 000 ml per day may possibly not be accompanied by clinical improvement Urinary tract infections during this period should be carefully watched for and treated In most of the cases of acute renal failure conservative measures of therapy as outlined above will suffice In situations complicated by severe trauma or infection where the protein catabolism is rapid and the clinical situation deteriorating the *artificial removal of metabolites* may be an important therapeutic adjunct and in some cases life saving Exchange transfusions peritoneal lavage and lavage of the large bowel have been reported with varying degrees of success Lavage of the small bowel by means of a double lumen in dwelling tube and the use of the artificial kidney which affects extracorporeal dialysis of blood appear to have been most successful in this regard Both procedures are effective only if utilized by experienced operators

Treatment of Chronic Renal Failure The patient with chronic renal failure too may have a remediable lesion In this regard interference with the bladder outflow or obstruction of the ureters due to metastatic carcinoma or endometriosis must be considered Potentially reversible renal involvement includes the metabolic disorders previously discussed having to do with calcium and phosphorus metabolism The state of chronic renal failure frequently manifests the many compensatory mechanisms which may adjust to slowly progressive

nitrogen retention An understanding of these mechanisms may help to prevent mistaking a compensatory adjustment for an "abnormality" (Chap 19) In the first stage of renal failure polyuria may result in large fluid losses Since at this stage the clinical situation has not markedly deteriorated the patient is subjectively able to regulate his own intake according to need Intake in this case prescribed by the physician should be aimed at replacement and an adequate urine volume rather than an attempt at forced diuresis There is evidence that the polyuria may be the result of an osmotic diuresis occasioned by the imposition of a relatively large solute load (per nephron) on remaining functional renal tissue This might account in part for sodium losses and would make of questionable value attempts to force a diuresis with large water intakes The inability of the kidney to substitute ammonia and hydrogen ion for sodium plus the large urine volume may result in sodium losses of considerable magnitude

In the so-called salt losing nephritis" which may represent a particular renal lesion rather than a phase of renal decompensation losses of from 12 to 15 Gm of sodium chloride per day have been described and added dietary salt must be given In the usual case of early polyuric uremia appetite is adequate to replace these losses by voluntary increases in intake Recurrent infection or a surgical procedure by interfering with voluntary intake *may result in negative balance In such patients* parenteral fluid and electrolyte therapy may bring about dramatic improvement Drastic restriction of sodium for the treatment of hypertension is obviously contraindicated in the presence of renal failure An occasional patient with renal failure loses large amounts of potassium and has symptoms of weakness fatigue and even flaccid paralysis which may be ameliorated by administration of potassium There is good evidence that among such patients some may have primary disease of the adrenal cortex manifested by hypersecretion of aldosterone In advanced severe chronic renal failure sodium therapy for hyponatremia may be evaluated in terms of etiology Chronically debilitated patients frequently show depressions of serum sodium level which are the result of disturbed equilibration between cells and extracellular fluid and are not amenable to replacement therapy On the other hand sodium depletion may produce hyponatremia which in itself may aggravate renal failure If this problem cannot be solved by clinical evaluation a cautious trial of sodium therapy is in order This is best given by mouth or failing this as 3 per cent solution intravenously Similarly the treatment of acidosis with sodium bicarbonate or lactate in the uremic patient necessitates a consideration of the development of the acidosis The retention of acid metabolite rather than loss of sodium may be at fault in which case alkali therapy would not be indicated Furthermore alkali therapy by depressing ionized calcium may produce tetany Unfortunately there are no rules of thumb by which the proper intake of sodium and water can be calculated In general the physician must seek to obtain some idea of the average output under optimal conditions of well being and attempt to regulate the intake accordingly Therapy aimed purely at correcting chemical evidence of dehydration or hyponatremia is often misdirected and must be guided by the principles mentioned above

Although in the experimental animal an increased protein intake may aggravate renal disease and hasten the progression of uremia precise evidence for this at the clinical level is lacking Thus a moderate intake of protein in chronic renal failure would seem advisable Some amount of exogenous protein is necessary to replace urinary and wear and tear losses and to supply enzyme and hormone building blocks Further the addition of some protein to an otherwise restricted diet makes the whole intake somewhat more palatable and thereby facilitates total caloric intake For the adult patient 0 5 to 0 7 Gm of protein per kg body weight seems a reasonable value in view of a possible marked difference between the dietary protein described and that actually ingested As in acute renal failure the protein sparing effect of nonprotein calories *is important In this instance however fat calories* become of much greater importance since with prolonged illness fat stores do become depleted Here the oral ingestion of an emulsified fat preparation may be of real value A supplement of emulsified fat and glucose (Lipomul) providing 400 calories per 100 ml and taken in 50- or 100-ml doses flavored with coffee extract or chocolate 5 i d may be a valuable caloric adjunct Aluminum hydroxide gels such as Basaljel in 30 ml doses 5 i d will decrease phosphate absorption and tend to ameliorate acidosis The treatment of chronic anemia should be guided by the precepts in the preceding paragraph The administration of cobaltous chloride no longer has a place in routine therapy Congestive heart failure should be treated as in other instances with the precautions mentioned for acute renal failure In this regard it is probable that the so-called uremic lung is largely if not entirely due to the pulmonary congestion of heart failure The use of paraldehyde and Sparine for sedation is of value Topical applications of dilute acetic acid solutions may be tried for pruritus Morphine should be used cautiously because of aggravation of itching and vomiting The treatment of nausea and vomiting by anything except restriction of all intake has rarely been successful although effective use has been made of chlorpromazine (Thorazine) in doses of

and the patient does not lose weight too much fluid has been given

Electrolyte requirements necessitate that the intake be potassium free since potassium intoxication is a potential hazard Chloride and sodium losses in the gastrointestinal tract should be replaced as indicated in view of the fact that more chloride is lost from gastric juice and more sodium from losses below the pylorus An increment of less than 1 Gm of sodium chloride for insensible loss may be added although this may be considerably larger in frank sweating In the author s view depression of serum sodium levels is not an indication for sodium therapy unless it can be proved that such levels are due to excess sodium loss Alternative explanations not requiring replacement therapy are intracellular movement of sodium metabolic readjustment of body fluid tonicity and dilution of concentrations by excess water production or administration The last is best treated by drastic water restriction as outlined above Infection should be vigorously treated since it results in increased protein catabolism The fact that there is no renal mechanism for the excretion of the chemotherapeutic agent chosen should be kept in mind In all cases adequate vitamin supplements should be given The administration of testosterone proprionate 50 mg a day may have value because of its anabolic effect *Congestive heart failure* must be treated in the usual manner (Chap 226) Improper fluid administration frequently precipitates this situation and it may be improved by restricting the fluid intake In many instances digitalis seems less effective than in congestive heart failure uncomplicated by uremia Because of the increased danger of arrythmias in uremic patients digitalis preparations should never be given intravenously The wisdom of treating mild to moderate degrees of *anemia* in the anuric patient by whole blood transfusion is in grave doubt In the author s view a hematocrit of 30 or less is the only indication for therapy which then should consist of small repeated transfusions of freshly drawn packed red blood cells

The hazard of *potassium intoxication* may be reduced by the use of cation exchange resin enemata Impaction of the material in the large bowel and the removal of sodium on the resin are problems to be considered Advanced degrees of potassium intoxication may be treated by hypertonic sodium bicarbonate sodium chloride and calcium gluconate and perhaps more effectively by the infusion of hypertonic glucose and insulin Where immediate treatment is necessary the sodium salts whose action is apparent in a matter of minutes should be used This consideration must be weighed against the potential hazard of giving a sodium load to an anuric patient The removal of potassium from the blood by use of the various forms of dialysis is more effective and of greater duration and may be employed when life is threatened For the symptomatic treatment of restlessness and convulsions rectal or intramuscular paraldehyde has been widely used magnesium sulfate intramuscularly (as discussed in Chap 227) may be more specific for the central nervous system manifestations Barbiturates if used should be of the variety metabolized by the liver (Seconal and Amytal) rather than those excreted by the renal pathway (phenobarbital barbital) Results with Promazine (Sparine) have apparently been extremely favorable During the *diuretic phase* the replacement of sodium and water losses should be influenced by the considerations mentioned previously Under these circumstances hyponatremia is a more valid indication for hypertonic sodium therapy The clinical response to such infusions may guide further therapy An occasional patient may retain sodium during the diuretic phase with a resultant marked hypernatremia and hyperchloremia This syndrome is frequently associated with central nervous system disturbances and a low urinary pH During the diuretic phase with volumes of urine greater than 1 500 ml per day dietary management need be less severe Under these circumstances the patient may be allowed by mouth anything which he desires and will tolerate It must be remembered however that urine volumes of less than 1 000 ml per day may possibly not be accompanied by clinical improvement Urinary tract infections during this period should be carefully watched for and treated In most of the cases of acute renal failure conservative measures of therapy as outlined above will suffice In situations complicated by severe trauma or infection where the protein catabolism is rapid and the clinical situation deteriorating the *artificial removal of metabolites* may be an important therapeutic adjunct and in some cases life saving Exchange transfusions peritoneal lavage and lavage of the large bowel have been reported with varying degrees of success Lavage of the small bowel by means of a double lumen in dwelling tube and the use of the artificial kidney which affects extracorporeal dialysis of blood appear to have been most successful in this regard Both procedures are effective only if utilized by experienced operators

Treatment of Chronic Renal Failure The patient with chronic renal failure too may have a remediable lesion In this regard interference with the bladder outflow or obstruction of the ureters due to metastatic carcinoma or endometriosis must be considered Potentially reversible renal involvement includes the metabolic disorders previously discussed having to do with calcium and phosphorus metabolism The state of chronic renal failure frequently manifests the many compensatory mechanisms which may adjust to slowly progressive

appears to remove enough metabolite to be of real value in the treatment of uremia

Homotransplantation of the human kidney is therapeutically successful only when performed between identical twins The possibility of effecting a "cure for chronic renal disease by modifying the fundamental response of the rejection of a homograft is an exciting prospect for the future

Section 4 The Respiratory System

The reader's understanding of the specific pulmonary disorders discussed in this section will be aided by prior perusal of Chaps 10 11 and 12 which deal with the common causes and mechanisms of such important manifestations as dyspnea cough hemoptysis and cyanosis Tuberculosis pneumonia and other specific infections of the lung are considered in the chapters on infectious diseases cor pulmonale and asthma respectively are discussed in Chaps 224 and 210 The treatment of chronic respiratory insufficiency will be found on p 1390 and acute respiratory failure is considered on pp 1392 and 1772

233 DISORDERS OF THE CHEST WALL AND MEDIASTINUM

John S Chapman

ANOMALIES AND DISORDERS INVOLVING CHEST WALL

The commonest anomalies of the chest wall are developmental abnormalities of the ribs which include bifidism agenesis of certain ribs cervical ribs and lumbar ribs Clinically these conditions are usually of little or no significance except as cervical ribs occasionally give rise to brachial plexus pain or obstruction of the subclavian vessels To the thoracic surgeon they may assume considerable importance in the planning of thoracoplasty The ribs are common sites for osseous metastases from visceral carcinoma and their involvement in multiple myeloma is usual The deeper muscles of the chest are invaded early by carcinoma of the breast and extension directly into bone may occur The skin of the chest wall may be involved in dermatomyositis and in scleroderma and extension of lupus erythematosus over the flush area of the upper chest may occur

Severe *scoliosis* or *kyphoscoliosis* is frequently associated with bronchiectasis on the compressed side while functionally the derangement of the thorax is a common source of dyspnea

Pigeon chest marked by a tremendous anteroposterior diameter of the thorax and a prominent prowlike sternum seems not to impair ventilatory or alveolorespiratory function and is clinically of importance chiefly in differentiation from the barrel chest of emphysema

Funnel chest is much more important from the standpoint of functional disorder On occasion the sternum may be so markedly depressed as to displace the heart into the left axilla while the rib motion is so much impaired that respiration becomes almost exclusively diaphragmatic This disorder which is apparently familial is readily recognized in early life and is amenable to various surgical procedures Results are most satisfactory if operation can be performed in childhood

Injuries of the thorax which are associated with multiple rib fractures or separation of the sternum from the ribs are of as much concern to the internist as to the surgeon The patient usually presents the picture of severe shock associated with marked embarrassment of respiration cyanosis and great pain One observes that the unsupported chest wall moves in a paradoxic manner the sternum or affected side being drawn inward during inspiration Numerous rhonchi are audible In addition traumatic pneumothorax with subcutaneous and

10 to 20 mg intramuscularly or 15 to 25 mg by mouth Moderate hypotension and drowsiness may be undesirable side effects The treatment of hiccough by carbon dioxide inhalation may be of temporary benefit In the absence of vascular disease the use of the artificial kidney in chronic renal failure may give striking but temporary remissions Homotransplantation of the human kidney has been attempted with recorded survival and adequate function for a period of 5 months in one instance This approach to therapy is interesting since it is aimed at curing chronic renal disease The complexity of the immune responses involved however makes it improbable that the procedure will be of more than temporary value in the near future In severe chronic renal failure particularly if accompanied by hypertension attempts at rigorous therapy may yield benefits not commensurate with the discomfort to the patient caused by enthusiastic efforts With this in mind the wise therapist may discontinue efforts at rigid dietary restriction parenteral supplements and painful procedures Not infrequently the wisdom of this choice may be manifest in a period of improved well being before the disease is mercifully concluded by a myocardial infarction or acute potassium intoxication

Extrarenal Removal of Metabolites in Uremia A number of techniques have been devised for the artificial removal of metabolites or toxic substances in cases of renal failure Of these the so called artificial kidneys are perhaps the most effective The artificial kidney is in reality a dialyzer and a number of different models have been constructed These vary in size and shape and in the manner of their construction but the fundamental principle of their operation depends upon the diffusion of substances from blood through a semipermeable cellophane membrane into a bath fluid so constituted that there is no diffusion gradient from blood to bath for substances whose removal is not desired Such a gradient from blood to bath is created for molecules whose removal is desired by omitting them from the bath fluid A major advantage of this technique is that each diffusible substance moves across the cellophane membrane primarily as a result of the concentration difference which exists on either side of the membrane and this transfer is independent of the concentration of other diffusible substances

Present indications are that such an apparatus may be used as an adjunct to good conservative measures of treatment in acute renal failure It should not be considered an alternative since the use of dialysis may greatly facilitate medical management by correcting the chemical imbalance decreasing nausea and vomiting and improving drowsiness and semicoma In acute renal failure complicated by fever infection or trauma where protein catabolism and consequent accumulation of metabolites are rapid conservative measures may be ineffective and actual removal by dialysis can be essential to treatment In this sense the use of dialysis to remove potassium in acute *spontaneous* potassium intoxication has a special significance

Other clinical situations in which dialysis has proved useful are the treatment of exacerbations of chronic renal disease and the preparation of the patient with chronic renal failure for surgical procedures In slowly progressing chronic renal failure hemodialysis in properly selected cases may give months of useful comfortable life after conservative measures have failed The type of case suitable for such treatment is the chronic uremic patient without significant hypertensive cardiovascular disease and with an adequate urine volume The removal of exogenous toxins in situations where renal function has failed may also be a useful function of the artificial kidney Such instances are aspirin poisoning and barbiturate intoxication in the presence of a renal function inadequate because of shock In bromide intoxication the artificial kidney has a particularly useful role since the predominantly extracellular position of the bromide ion makes it easily removed by dialysis and because resorption of filtered bromide by the normal renal tubule makes the usual methods of treatment slow The use of the various forms of artificial kidneys should not be reserved for terminal moribund patients since experience indicates that it has a real role in therapy which is best performed in conjunction with other forms of treatment Artificial kidneys operated by trained and experienced teams with adequate facilities in large centers may serve as a source to which may be referred patients for whom conservative methods of therapy alone are not adequate Although simpler cheaper artificial kidneys may be built there is no inexpensive way to construct a physician well versed in the complex problems of its use

The use of peritoneal irrigation by older techniques employing operative procedures on the abdomen have now largely been abandoned since use of this procedure must necessarily be prolonged in order to achieve effective nitrogen removal and this almost inevitably led to infection Simpler methods over shorter periods however have been devised employing plastic tubes in conjunction with ordinary parencentesis techniques Such methods are effective in correction of electrolyte abnormalities although of much less value in the removal of other metabolites The relative simplicity of the technique however makes it a useful one in small hospitals Lavage of various portions of the intestinal tract employing a number of different techniques has been reported When used with care and by trained teams lavage of the small intestine

usual etiology of dyspnea is concerned On fluoroscopy the diaphragm is seen to present a very rapid jerky incoordinate motion The condition may develop quite suddenly and cease equally rapidly The cause of the phenomenon is not known but it is thought to arise from some type of phrenic nerve or muscular irritation not unlike the mechanism involved in hiccough

DISEASES OF MEDIASTINUM

The only tissue that can be considered truly mediastinal is the loose areolar tissue and fat which lie among traversing structures In health the mediastinal structure is so elastic that displacement readily occurs from slight changes in pleural pressure and even from a change from one lateral decubitus to the other *Mediastinal shift is common* in diseases of the lung or pleura and takes place when pneumothorax is present for long periods Variation of position of the mediastinum with phases of respiration indicates either unilateral air trapping blocked bronchus or fibrosis of the lung

Mediastinitis

Primary syphilitic mediastinitis and tuberculous mediastinitis have been described and other primary infection may occur A type of mediastinitis associated with viral invasion of the tracheobronchial tree is recognized infrequently but in fact, may be quite common The organism probably reaches the tracheobronchial nodes where it sets up a lymphadenitis that results in fever a sense of retrosternal oppression and poorly localized pain in the center and upper portion of the chest Since the enlargement of the lymph nodes is so slight the condition is not evident in roentgenograms and one can only suspect its existence It is fairly well substantiated by autopsy that mediastinal lymphadenitis whatever the infecting agent may well be the precipitating factor in the development of pericarditis

The more dramatic type of mediastinitis a spreading pyogenic inflammation or acute abscess is the result either of severe derangement of the organs which lie within the mediastinum or of descending infection from acute retropharyngeal or cervical abscess The disease is marked by high fever marked retrosternal pain which may be referred to the back, difficulty in breathing a cough of a pressure type and dysphagia At times films at various angles fail to demonstrate clearly the inflammatory process in which case diagnosis is most difficult in other cases roentgenograms may reveal considerable widening of a portion of the mediastinum and even the fluid level of abscess In every patient with cervical or retropharyngeal abscess the physician should keep in mind the possibility of mediastinitis and should be on the alert for symptoms

Although diseases (notably cancer) of the bronchus may rarely perforate and lead to mediastinitis the most common cause by far is disease of the esophagus Perforation may result from missiles from rough instrumentation from attempted dilatation of strictures and even when the greatest care is used from passage of the esophagoscope into pouches or diverticula Spontaneous perforation may follow neurosurgical procedures and spontaneous rupture may occur during retching and vomiting Ulceration is seen in association with peptic esophagitis with severe burns involving a large area of the body surface (*Curling's ulcer*) and above all, with carcinoma of the esophagus

In all these situations the patient presents the *picture of severe acute illness superimposed on* cachexia, if carcinoma is the cause or associated with shock in the event of acute perforation Gases at once enter the mediastinum along with infected secretion and may produce Hamman's sign. If the volume of gas is large it may dissect its way into the neck where subcutaneous emphysema will be demonstrable Pain is frequently intense and may radiate to the back or upward into the neck

X ray recognition depends upon the demonstration of streaky or patchy translucent areas overlying the mediastinal structures In patients who survive long enough widening of the mediastinum and fluid level may be present

Surgical exploration and drainage is urgently indicated, with repair of the defect if its nature permits Penicillin in doses of 10 million units daily is necessary

Pneumomediastinum

This condition may be either traumatic or spontaneous The escape of gases into the mediastinum is also frequent in perforation of the herniated stomach or of the esophagus Traumatic pneumomediastinum is usually associated with chest wall injury of considerable magnitude In patients who have suffered trauma, the escape of gas is rapid and dissection through the mediastinum into the neck occurs within a short time Hamman's sign, a to-and fro crunching, clicking or tapping (as variously described) is audible over the precordium The cardiac dullness is reduced in area and the heart sounds commonly are distant Crepitation of the subcutaneous tissue is readily palpable in the neck and sometimes over considerable areas of the body The x ray reveals extensive widening of the mediastinum, with large streaks of gas separating the major structures

Neither the pneumomediastinum nor the subcutaneous emphysema constitutes a very serious threat to the patient, though disfigurement may be severe

mediastinal emphysema frequently is seen as a result of laceration of the lung Hemoptysis and bleeding into the pleural cavity are by no means rare

The patient s condition requires immediate and well considered measures Shock and hemorrhage call for transfusion of whole blood Tension pneumothorax if present demands immediate decompression even with the use of continuous suction if the escape of air is rapid The presence of blood and secretions in the airways necessitates bronchial aspiration at frequent intervals Although one or two injections of morphine may be necessary during the acute emergency this drug should be discontinued as soon as possible since its depressant action on the cough reflex and the respiratory center tends to perpetuate and aggravate both bronchial obstruction and hypoxia Intercostal nerve block successfully performed is far more efficient in relieving pain and has none of the disadvantages of the use of narcotics As the patient emerges somewhat from severest danger the problem of the immobilization of the flailing chest wall arises Heavy adhesive strapping markedly limits the motion of the chest wall but is a potent cause of retained secretions Sandbags offer quite as good immobilization without such great danger of atelectasis and pneumonia In extreme cases surgical fixation may be necessary to control paradoxic motion

Fractures involving the first rib on either side may have two grave complications Laceration of trachea and esophagus may occur with formation of tracheoesophageal fistula The subclavian vessels may undergo trauma from broken rib ends and traumatic aneurysm or arteriovenous fistula result

Another complication of severe trauma to the chest wall is laceration or even division of a major bronchus The condition must be suspected if following removal of gas and blood breath sounds remain absent and the side continues to exhibit radiologic opacity The recognition is important since bronchoplastic procedures result in recapture of completely normal function Planigraphic study of the major bronchial area reveals absence of the usual bronchial lucency while iodized oil demonstrates that the main bronchus ends blindly It is noteworthy that such bronchial injury may result occasionally from apparently trivial trauma

Infections of the chest wall are rarely of much moment but on occasion severe phlegmons may develop along the tract of an aspirating needle Tuberculous and actinomycotic pleurocutaneous fistulas may result either from repeated aspiration or rarely spontaneously Ribs cartilages or sternum are fairly frequent sites of tuberculous osteitis

Tumors of the chest wall commonly arise either from intercostal nerves or from ribs Fibromas sometimes persisting in benign form only to undergo sarcomatous degeneration later have been described

If the diaphragm may be considered a part of the chest wall its commonest disorder is *hiatus hernia* (see Chaps 4 244) Traumatic hernias occur chiefly on the left side and give rise to a confusing picture characterized by the manifestations of an acute surgical abdominal disorder as well as by those of acute respiratory embarrassment The involved side of the chest is motionless and breath sounds are absent but one may hear peristaltic sounds sometimes as high as the clavicle The roentgenogram of the chest commonly reveals marked shift of the heart and mediastinum into the normal side of the chest on the other dense side small radiolucent areas sometimes with fluid levels indicate the presence of bowel above the diaphragm A glass of barium suspension followed fluoroscopically will serve to remove any doubt

Eventration of the diaphragm a congenital anomaly usually involving the posterior leaf of the left half of the diaphragm may be mistaken on physical examination for pleural effusion or diaphragmatic elevation following phrenic paralysis Roentgenographically before the lateral view clearly reveals the nature of the lesion the suspicion is of hernia or phrenic paralysis

Paralysis of the diaphragm is of very great importance both from a functional and from a diagnostic point of view The diaphragm accounts for about two thirds of the ventilatory function and its paralysis may result in considerable embarrassment of respiration Paralysis has to be differentiated from eventration and from fixation by adhesions The discovery of paradoxic motion of the muscle when during fluoroscopy the patient sniffs indicates interruption of the phrenic nerve which has been a collapse measure frequently employed in tuberculosis Paralysis however may be the result of direct invasion of the nerve by carcinoma of the bronchus Rarely it may occur spontaneously as a result of twisting motion of the head and neck with the thorax in a strained position In the presence of what appears to be a spontaneous paralysis without evidence of tumor it is very important to be sure that the elevation of the diaphragm is not apparent Pleural fluids now and then accumulate beneath the lung and fail to take the ordinary meniscus curve on physical examination or x ray study Patients of this type frequently fail to show any motion of the supposed diaphragmatic shadow but before making a definite diagnosis of spontaneous paralysis one should attempt thoracentesis to make certain that the shadow is not produced by subpulmonary fluid

Diaphragmatic flutter is a rare phenomenon in which a patient complains of marked shortness of breath without apparent cause in so far as the

This space contains the aortic arch and its major branches (innominate, left subclavian and left common carotid origins), the innominate veins and the upper half of the superior vena cava, the trachea, esophagus, thoracic duct, thymus gland, some lymph nodes and the vagus, phrenic, left recurrent and cardiac sympathetic nerves.

To be found in the superior compartment are bronchogenic cysts, tuberculomas, thyroid and parathyroid adenomas, teratomas and metastatic tumors.

The *anterior* mediastinum is demarcated in front by the sternum, posteriorly by the pericardium and below by the diaphragm. It is a very meager space and contains normally only some areolar tissue, lymphatics, lymph nodes and branches of the internal mammary arteries.

In this space may be located teratomas, thymomas, lymphangiomas and any of those listed for the superior mediastinal space.

The *middle* mediastinum comprises the heart and its pericardial covering, the ascending aorta, the lower portion of the superior vena cava and its junction with the azygos vein, the bifurcation of the trachea, the proximal pulmonary arteries and veins, the phrenic nerves and some lymph nodes.

In this compartment may be found bronchogenic cysts and pericardial cysts or diverticula.

The *posterior* mediastinum is bounded in front by the heart, in back by the lower eight thoracic vertebrae and the shelving posterior portion of the diaphragm. It contains the thoracic descending aorta, the azygos and hemiazygos veins, the esophagus, the thoracic duct, the vagus and splanchnic nerves and some lymph glands.

In the posterior mediastinal compartment are typically found neurogenic tumors and also certain bronchogenic, esophageal and gastroenteric cysts.

Symptomatology. A majority of benign mediastinal tumors are asymptomatic and are discovered in the course of routine roentgenograms or those done for other purposes. With very few exceptions symptoms are not specific and are caused by complications which include pressure necrosis, secondary infection, hemorrhage and rupture of cystic lesions into a neighboring viscus. Thus fever, cough, dyspnea, wheezing, chest pain and hemoptysis may occur in any combination and sequence. Dysphagia is not a very common symptom.

Malignant tumors which invade extensively in the mediastinum tend to produce the so-called *syndrome of the superior vena cava*. This is manifested by edema of the neck, face and conjunctiva together with distention and increased pressure in the veins of the neck, chest and upper extremities. Epistaxis may occur, and also hoarseness from laryngeal edema or paralysis of the recurrent nerve. The patient may have severe headache,

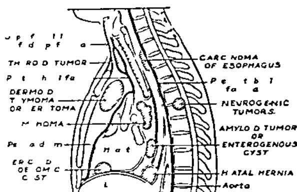

FIG 166 A much simplified lateral projection of the chest showing sites of predilection of various mediastinal tumefactions. (*Courtesy Dr John Chapman.*)

fainting spells and vertigo. This syndrome sometimes occurs with very large benign tumors such as thyroid adenoma, located in the superior aperture of the thorax.

One pathognomonic symptom of a particular mediastinal tumor is *trichoptysis* or the spitting up of hair, usually accompanied by sebaceous material. This occurs in the case of dermoid cysts, but only when fistulization into the tracheobronchial tree has taken place.

Differential Diagnosis. Certain lesions originating in structures outside the mediastinum proper can intrude themselves secondarily and give rise to confusion in diagnosis. Such include (1) substernal goiter, (2) diaphragmatic hernias, (3) tumors arising in the thoracic skeleton and (4) thoracic meningocele. In addition, aneurysms of the heart, aorta and great vessels and pericardial effusion may simulate tumor.

Substernal goiter usually arises as a nodular downward extension from a lower thyroid pole. There may be a palpable mass in the neck, the trachea tends to be compressed and deviated away from the side of the lesion. Radiographic continuity of the mediastinal mass with a cervical thyroid shadow is commonly seen. Radioactive iodine tracer techniques may be useful in doubtful cases.

The *diaphragmatic hernias* most likely to be confused with mediastinal tumor are those located in the parasternal foramen of Morgagni. These may be essentially solid lesions consisting of herniated omental fat. In the lateral radiographic projection they are based strictly in the anterior cardiophrenic angle. The air pattern of the transverse colon may be abnormally elevated; this can be further demonstrated by barium enema.

Chondroma, chondrosarcoma and *Ewing's sarcoma* arising in rib or vertebra may grow internally and expansively in certain cases. Careful roentgenologic study of the involved bone should lead to the detection of some changes, but these may be quite

at the time Only rarely is it necessary to make incisions about the base of the neck to permit the escape of gases Rather the attention should be directed to the chest wall and the pulmonary injury Infection seems to be quite rare

Spontaneous pneumomediastinum is said to occur predominantly in young males who previously have been in excellent health The pathogenesis as described by Macklin is the escape of air from the alveoli into the perivascular tissue of the lung from which the gas makes its way into the mediastinum The onset is sudden usually with severe pain retrosternally and often with radiation into the neck shoulders or arms so that coronary occlusion stands high in the differential diagnosis

The direct diagnosis depends upon the discovery of the crunch which is said to be audible in some patients only when they are placed in certain positions In a fairly high proportion of patients left sided pneumothorax may be demonstrable also

The radiographic signs of small pneumomediastinum are said to be unusual prominence of the aortic knob a very clear outline of the pulmonary arterial segment or a band of radiolucency lying along the border of the heart Most competent radiologists insist upon more definite signs than these—i e the demonstration of streaks or patches of gas in the mediastinum The usual projection is inadequate and oblique and lateral films at full expiration often prove more informative Since small left pneumothoraxes alone may produce a crunch indistinguishable from Hamman s sign conclusive proof of pneumomediastinum depends upon the elicitation of the crunch in the absence of a pneumothorax or upon the absolute demonstration of mediastinal gas by roentgenogram No treatment other than rest reassurance and mild analgesics is required The patient should be warned that the accident might recur

Tumors of the mediastinum are discussed in Chap 234

234 TUMORS OF THE MEDIASTINUM

Gustaf E Lindskog

Mediastinal tumefactions may be classified according to their pathogenesis as follows true neoplasms (e g thymoma) congenital malformations (e g bronchogenic cysts) infections (e g tuberculomas) and degenerative lesions (e g arteriosclerotic aneurysms) True neoplasms may be primary or secondary and benign or malignant

Within the narrow confines of the mediastinum even the most benign and slowly growing tumor can on occasion produce irreparable damage to the host by mechanical encroachment compression and obstruction of vascular channels the esophagus and the tracheobronchial tree Infection may develop in cystic lesions from blood borne sources or by direct extension after erosion into the bronchi or into the esophagus A comprehension of mediastinal anatomy is therefore essential to the study of mediastinal tumors furthermore any attempt to define the pathologic nature of these lesions before surgical excision must lean heavily on their location in the mediastinal compartments since the different varieties of tumor have definite sites of predilection (Fig 166)

Anatomy of the Mediastinum The mediastinum as the name implies is a space lying between the right and left pleurae in or near the median sagittal plane of the thorax More for clinical purposes than for anatomic reasons the mediastinum has been divided into four compartments superior anterior middle and posterior

The *superior* mediastinum is bounded in front by the manubrium and behind by the upper four thoracic vertebrae Inferiorly it is demarcated by an imaginary line extending from the manubriogladiolar juncture to the fourth vertebral body

a sympathoma of neurofibromatous type (4) sympathicoblastoma, derived from primitive cells which are small, round, densely nucleated and with a tendency to pseudorosette patterns (5) paraganglioma including the rare hypersecreting variant pheochromocytoma

About 95 per cent of posterior mediastinal tumors are neurogenic in derivation, but neurilemmoma and neurofibroma may occur in a more lateral or peripheral situation in relation to the intercostal nerves An expansile growth located in an intervertebral foramen may enlarge the latter as demonstrated in roentgenograms by intrusion into the epidural space it can produce symptoms of spinal cord compression the so-called "dumbbell tumor

Ganglioneuromas exist principally in relation to the sympathetic chain and can produce the typical Horner s syndrome and sweating changes of the ipsilateral upper extremity Neurofibroma may be a local manifestation of von Recklinghausen s disease

Tumors of the Thymus. Tumors arising in the thymus gland are frequently difficult to identify and classify The two main cell types thymocyte (lymphocyte?) and reticulum (epithelial?) may be present in varying proportions Thymomas tend to be heavily encapsulated and lobulated fleshy or solid Microcyst formation is common but gross cystic changes can occur Microscopically perithelial arrangement of tumor cells around vascular lymphatic, or tissue spaces is rather characteristic Hassal s corpuscles are found in only about 25 per cent.

Malignant change in a thymic tumor is signaled by capsular infiltration and invasion of contiguous structures such as pericardium trachea, large vessels and pleura. Remote metastases are uncommon even in fatal cases

Thymic tumors are found in 15 to 20 per cent of myasthenia gravis cases and a significant number of patients with thymic tumors on careful analysis are noted to have myasthenic symptoms Thymectomy and excision of thymic tumors have an unpredictable effect upon the course of myasthenia gravis ranging from cure to no effect

Other Generally Benign Tumors of the Mediastinum Lipomas and fibromas are relatively rare They occur anywhere in the mediastinum and furnish the largest specimens some have been reported as heavy as 17 pounds Pressure symptoms are disproportionately mild

Lymphangiomas are typically cystic and located in the anterior mediastinum and cardiophrenic angle They are multilocular and demonstrate elastic tissue and smooth muscle in association with the mesothelium lined channels Cervical and mediastinal locations may be combined in the same case Spontaneous chylothorax has been reported and secondary infection but ordinarily these are asymptomatic tumors

Parathyroid adenomas usually occur in the expected distribution of the normal parathyroid glands In perhaps 20 per cent of cases they are located ectopically in the mediastinum Such adenomas are ordinarily quite small and are not often visualized by radiographic methods An outline of the esophagus with barium may be helpful The surgical treatment of hyperparathyroidism requires a complete search of the cervical area before the mediastinum is explored ideally in a single operation

Pericardial (Pericardiodiaphragmatic) Cysts and Diverticula Aberrations in the development of the pericardial sac may lead to the formation of pericardial diverticula or cysts These are unilocular thin walled sacs containing clear colorless fluid A simple endothelium lines the thin connective tissue wall Diverticula are rarer than cysts they communicate by a narrow ostium with the main pericardial sac whereas the cysts are separate and may even be at some distance from the pericardium They produce no symptoms as a rule and are removed only for diagnostic purposes

Primary Malignant Tumors The lymphoblastic series of tumors (lymphoma Hodgkin s disease and lymphosarcoma) constitute about 70 per cent of this category Various types of connective tissue malignancies also occur such as fibrosarcoma. Epithelial neoplasms independent of any demonstrable extramediastinal focus (such as the peripheral lung) are least common Some of these rarities may arise from the thymus from pharyngeal pouch remnants, or from degenerating teratoid lesions.

Hodgkin s disease (see Chap 220) may begin in the mediastinal nodes and remain apparently localized there More commonly there is relatively early involvement of the cervical, axillary or other peripheral lymph nodes this enlargement may constitute the first clinical evidence of the disease Splenomegaly occurs in about 70 per cent of Hodgkin s cases at some time in the course There may be itching of the skin. Systemic manifestations such as periodic fever malaise anorexia, and weight loss are more common with Hodgkin s disease than with lymposarcoma and reticulum cell sarcoma. The latter is sometimes confined to the region of the thymus when first recognized, only to spread later and produce the clinical picture of superior vena caval obstruction Pleural effusion may develop

Secondary Malignant Tumors The commonest tumor of the mediastinum is undoubtedly metastatic carcinoma. The site of origin may be an intrathoracic organ such as esophagus trachea, or

inconspicuous Pain is likely to be severe with malignant bone tumors and can simulate that caused by neurogenic tumors when it is segmental in type

Thoracic meningocele is a very rare lesion seen chiefly in middle aged females and associated with von Recklinghausen s disease (*café au lait* spots and multiple neurofibromatosis) Radiographic examination of the spine shows enlargement of several inter vertebral foramina

Aneurysms of the aorta and its major branches are of great concern in the differential diagnosis of mediastinal tumors They are discussed in Chap 229

Large *pericardial effusions pericardial cysts* and *idiopathic cardiac* hypertrophy may be confused radiologically and clinically with mediastinal neoplasms

Diagnostic Methods Physical examination should include a careful study for enlarged peripheral lymph nodes especially in the supraclavicular and axillary groups and for splenomegaly and hepatomegaly in connection with the malignant lymphomas Recurrent nerve paralysis should be ruled out by indirect laryngoscopy *Horner s syndrome* is usually a stigma of malignant infiltration of the upper dorsal sympathetic chain but may occur as a pressure effect from discrete and benign tumors This syndrome is characterized by narrowing of the palpebral fissure recession of the eyeball a contracted pupil and absence of sweating on the ipsilateral side of the face

Bronchoscopy is rarely of definitive value in the diagnosis of primary mediastinal tumors but may be required to rule out lesions such as bronchogenic carcinoma Bronchography employing iodized oil is neither helpful nor necessary unless obstructive complications in the lung require evaluation Sometimes the latter are at least as demanding of therapy as the causative tumor

A complete radiologic study includes fluoroscopy lateral and oblique roentgenograms as well as the standard PA projection A barium study of the esophagus should be carried out in every case of aneurysm and in the case of all tumors of the middle and posterior compartments Laminagrams may be very helpful The radiologist tries to determine among other things the presence or absence of encapsulation the existence of calcifications air and fluid levels intrinsic or extrinsic pulsations and the movement of the lesion during respiration and deglutition Of greatest importance is the position of the lesion in the mediastinal compartments characteristic locations are described under *Anatomy*

Surgical excision of a cervical axillary or other enlarged lymph node may be of great diagnostic value particularly when such diseases as Hodgkin s *tuberculosis and Boeck s sarcoid* enter the differential diagnostic picture

Even when lymph node enlargement is not detectable it is sometimes possible to establish a tissue diagnosis after *en bloc* resection of the small lymph nodes in the fatty tissue overlying the scalenus anticus muscle near its insertion

The commoner types of mediastinal tumors will be discussed briefly in terms of their special characteristics

Teratoid Tumors Benign teratoid tumors are commonly called dermoids They are usually large when first recognized ordinarily in the third and fourth decades More often unilocular than multilocular they contain sebaceous material and hair Dental structures and bone are sometimes present and cause characteristic radiographic densities The more complex teratomas are fleshy and contain *tissue recognizable as nervous system intestinal* tract pancreas kidney or testis and the like The capsules may be ill defined and infiltrated by carcinomatous or sarcomatous cells A predominantly unilateral development may lead to confusion with such tumors as seminoma and chorionepithelioma The complex teratomas have a very high incidence of malignant change with local invasion and metastases

Bronchogenic, Esophageal and Gastroenteric Cysts These are developmental anomalies of the primitive foregut and bronchial buds Commonly unilocular they are chiefly located in relation to the trachea upper bronchi and esophagus rarely they are found in the periphery of the lung or upon the diaphragm Communication with the air passages may preexist or develop later because of pressure The result is *pyocyst* and this may be associated radiographically with an air fluid level simulating pulmonary abscess

The majority of these cysts have a respiratory type of epithelial lining with ciliated columnar cells and pseudostratified basilar nuclei smooth *muscle cartilage and mucous glands may be present* Squamous and gastrointestinal types of lining cells are occasionally encountered principally in the cysts located about the distal esophagus The gastrointestinal types are prone to give rise to serious symptoms in the first year of life the others in adult life

Neurogenic Tumors Neurogenic tumors are the most frequently encountered of primary mediastinal neoplasms Several pathologic types are recognized (1) neurilemmomas derived from the sheath cells of Schwann (2) neurofibroma a more complex but usually benign lesion showing in addition to Schwann cells neuraxones and proliferated connective tissue (3) ganglioneuroma with ganglion cells in variable stages of maturity interspersed in

tuberculosis and actinomycosis Extension of infection through the diaphragm either by way of lymphatics or through direct erosion may produce pleurisy Commonly involving the right pleura particularly are amebic and bacterial abscesses of the liver a subphrenic collection of pus resulting from a perforated viscus and perinephric abscesses may be associated with pleural inflammation

Infarcts of the lung since they involve terminal vessels have at least one base on the pleura and sometimes two The pathologic changes produced therefore rather regularly involve the visceral pleural surface and result in the formation of fluid

Neoplasms of the lung either by metastasis or direct extension commonly reach the pleural surface and excite reaction whereas metastases from distant organs may seed the pleura directly or as in the case of carcinoma of the breast extend through the chest wall to produce disease of the parietal pleura

Finally collagen disease is frequently associated with pleurisy along with involvement of other serous cavities Typical of this group is disseminated lupus erythematosus but pleural disease may also be a feature of scleroderma and rarely, it may be associated with active rheumatoid arthritis In severe phases of active rheumatic heart disease the pleura may undergo similar reaction to that seen in the pericardium

The first pathologic change in acute pleuritis is redness edema and opacification of the surface followed soon by deposition of fibrin flakes over the center of the inflammation Such changes are manifest clinically as acute dry pleurisy The physical finding which corresponds with this phase of pleurisy is the coarse to and fro friction rub roentgen findings are not evident until fluid begins to accumulate in the pleural sac

As the disease progresses the acutely inflamed pleura begins to throw out an exudate which is at first usually serofibrinous Arrest of the process may take place either at the dry stage or at this stage but in the case of suppurative infections the fluid rapidly takes on the aspect of pus as greater numbers of neutrophils and large quantities of fibrin make their appearance In either the serofibrinous or purulent phase there is usually generalized chest pain frequently most severe in the lower thorax Dyspnea not only expresses voluntary and involuntary splinting of the chest but may be a result of considerable quantities of fluid Characteristic physical signs include a shift of the heart and mediastinum to the opposite side flatness and usually greatly diminished or absent breath and voice sounds The discovery of pleural fluid demands thoracentesis

The final or healed phase of any of these pleural reactions whether wet or dry serofibrinous purulent or bloody is the organization of pleural exudate The degree and extent of the resultant fibrous or adhesive pleurisy depend upon the amount of fibrin in the thorax and its distribution A small area of acute dry pleurisy may have as its residue only a thin filmy adhesion or as in the case of a tuberculous nodule a short thick cord Pleurisy that has produced great quantities of fibrinopurulent exudate or that has been associated with a considerable amount of bloody fluid may on the other hand give rise to marked pleural thickening with contraction of the entire hemothorax marked retraction of the heart and mediastinum into the affected side and elevation and fixation of the diaphragm Other physical findings consist of flatness to percussion very distant breath sounds and reduced tactile and vocal fremitus The condition is to be distinguished from acute pleurisy with effusion by the retraction and fixation of the affected side On roentgenographic study the displacement of the heart and mediastinum elevation of the diaphragm narrowing of interspaces and partial opacity of the lung field are characteristic In such instances particularly if the cause of the fibrothorax has been either tuberculous empyema or hemothorax extensive calcification of the pleura may be a late result A lung so encased may be almost without function

Inflammatory Pleural Fluids For purposes of this discussion all fluid that reveals the presence of inflammatory cells even though they are relatively few and even though the stimulus may be so comparatively innocuous as a small amount of blood in the pleura will be regarded as exudates Pathologically such differentiation is correct it avoids the uncertain terms *exudate* and *transudate* which could be clinically realized only by ignoring the numerous instances in which fluids manifested some characteristics of each type

It is more useful to describe characteristic inflammatory fluids than to attempt to set arbitrary and unreliable standards of differentiation One extreme of inflammatory pleural fluid is that associated with pneumonias The material obtained consists of pus has a high specific gravity may coagulate and contains innumerable cells An intermediate serofibrinous fluid such as may be encountered in tuberculous pleurisy or in a partially treated pneumonia is likely to have a specific gravity of around 1 018 a protein content of 1 5 Gm or more and cells numbering from 200 to 2 000 varying from a slight preponderance of polymorphonuclear cells to a vast preponderance of lymphocytes The other extreme consists of a thin fluid with a specific gravity sometimes as low as 1 012 with very little protein but with perhaps as many as 200 to 300

bronchi Mammary cancer is a frequent invader however and remote neoplasms such as renal and ovarian carcinoma may metastasize to lymph nodes and subsequently extend more diffusely in the mediastinal tissues

Extension to mediastinal lymph nodes is an important limiting factor in the surgical treatment of mammary carcinoma Its frequency has led to the recommendation that preliminary biopsy of the internal mammary chain of nodes be performed in cases where the primary breast lesion is situated in the medial quadrants and when the axillary lymph nodes are palpably involved

Isolated lymph node metastases in the mediastinum may be quite asymptomatic As enlargement and infiltration occur manifestations of pressure and pain may develop and the syndrome of superior vena caval obstruction (q v) is not infrequently observed

Treatment of Mediastinal Tumors Benign mediastinal neoplasms cannot be differentiated accurately by clinical and radiographic methods from localized malignant forms Therefore the indicated therapy is surgical exploration and excision unless there exists some compelling reason to the contrary such as extreme old age or coexisting disease which itself has a lethal prognosis

The most useful exploratory incision is a long posterolateral one with rib resection since technical problems may be considerable Certain anterior tumors can be reached by medium sternotomy or parasternal chondrectomy Ideally the tumor should be totally extirpated in a single stage Certain large and infected cystic tumors in poor risk patients may be marsupialized for drainage and resected at a later date

The mortality rate for excision of benign and localized malignant mediastinal tumors is less than 5 per cent and in some reported series approaches zero

Invasive malignant neoplasms can only be biopsied or partially resected An attempt should be made to recognize these unfavorable cases by careful physical examination and to obtain tissue for microscopic study by simple techniques such as needle biopsy and the like When these fail a mediastinotomy may be required It is important not to treat a suspected lymphoma or other mediastinal neoplasm by radiation until a tissue diagnosis is established There are many pitfalls in so-called diagnostic radiotherapy

Hodgkin s disease confined to a local area should be treated with heavy doses of radiation and in a rare case this may be combined with surgical excision Widely disseminated tumors must be palliated with smaller doses of roentgen rays and such chemotherapeutic agents as the nitrogen mustards

235 DISEASES OF THE PLEURA

John S Chapman

Upon being confronted by a complaint of chest pain one s first consideration must be to determine if that pain arises as a result of pleural disease In the differential diagnosis one must exclude disease of the heart and great vessels the esophagus the chest wall the spine the spinal cord the intercostal nerves and the abdominal viscera while at the same time one must be familiar enough with reference of pain (see Chap 4) to appreciate that pleural pain may be referred to the abdomen or that it may radiate to the neck (diaphragmatic pleurisy) In addition to eliciting a careful description of the pain one must be diligent in examination of the chest wall its muscles and bones Quite frequently the pain of fractured rib particularly if it occurs as a result of hard and chronic cough is indistinguishable from pleurisy unless one exerts a springing pressure upon the sternum which results in instant severe sharply localized pain Similar maneuvers will elicit the pain that results from separation of the costal cartilage from rib a condition in which radiography is of no advantage Careful palpation elicits a point localization and may reveal offset or fusiform swelling at the costochondral junction

INFLAMMATION OF THE PLEURA

Pleuritis is rarely a primary disease but results from extension of infection from contiguous areas The most direct source obviously is the lung and inflammation of the pleura is common in such diseases as the various bacterial pneumonias abscess

prolonged medical therapy or comparatively early decortication (i e as soon as the active inflammation has subsided) In these refractory inflammations the use of streptokinase and streptodornase may be undertaken Their administration is usually followed shortly by high fever and perhaps a rapid increase in the amount of fluid in the pleural cavity For this reason an intercostal catheter is frequently introduced into a previously determined pleural pocket and the enzymes introduced through the catheter which is then clamped for 12 hr At the end of the period it is unclamped and connected with an underwater seal to a drainage bottle The procedure may be repeated in 3 or 4 days

If marked reexpansion of the lung does not occur within 2 weeks of such treatment the catheter should be removed and the process allowed to proceed to its natural culmination Although many patients at this point may present very disappointing radiographic results considerable clearing may take place slowly over a period of several months Surgical decortication may then be considered in the light of the remaining pleural masses and the effect of the disease process on pulmonary function

The presence of a pleural fluid level in chest films indicates the presence of both fluid and air and establishes bronchial pulmonary or esophageal communication with the pleura An open bronchopleural fistula should be considered in every case and at the first aspiration of fluid 1 ml of methylene blue should be injected into the pleura but no other substance If blue dye appears in the sputum (occasionally it is necessary to bring out the blue color by means of hydrogen peroxide) open surgical drainage becomes an emergency measure And as long as any possibility of fistula exists no fluid of any sort should be injected into the pleural space but rather the sac should be kept as nearly dry as possible and the patient urged to lie on his affected side

PNEUMOTHORAX AND HEMOPNEUMOTHORAX

Pneumothorax Spontaneous pneumothorax may be either primary or secondary to some evident disease of the lung When obvious cause is apparent on physical roentgenographic or laboratory examination it is usually either tuberculosis abscess or carcinoma but occasionally generalized bullous emphysema is the causative disease In all these instances the problem is much graver than in primary spontaneous pneumothorax not only because of the gravity of the underlying disease but also by reason of the strong probability that the opening through the pleura may persist that escape of air into the pleura may continue that infection is almost certain to occur and that as a result of all these facts the lung can be reexpanded only with the greatest difficulty The signs and symptoms are the same as those given below for uncomplicated primary spontaneous pneumothorax Treatment also is essentially the same as that given for the primary condition except that in these instances large doses of antibiotics are strongly indicated For consideration of tuberculous spontaneous pneumothorax with empyema and persistent bronchopleural fistula see Chap 141 Particularly in the case of putrid abscess with associated large empyema and patent bronchopleural fistula there is urgent need of open surgical drainage to manage both the abscess and the empyema as well as to prevent spill over into healthy lung tissue

The cause of primary spontaneous pneumothorax is thought by most authorities to be the rupture of subpleural bullae or blebs The exact mechanism of rupture is not known but in most cases it is evidently not a result of exertion The bullae or blebs are believed to arise as a result of localized obstructive bronchitis and to constitute in fact very limited areas of emphysema If there is associated fever and formation of serofibrinous exudate there is reason to regard these pneumothoraxes as resulting from inapparent tuberculosis of the lung Other findings that are regarded as being indicative of tuberculosis are numerous apical adhesions though this rule is by no means infallible

The escape of gas into the pleural cavity usually is associated with marked pain which may be felt in any part of the chest on the affected side or referred to the neck or abdomen Such pain is aggravated by any physical exertion and mildly by respiration but the pain may increase rather steadily in the absence of physical activity As a rule when the patient is put to bed pain subsides within 24 to 48 hr after the onset Dyspnea develops early as a result of pain but becomes more intense later if the accumulation of pleural gas produces positive pressure (tension pneumothorax)

On examination the affected side appears full and motionless and it is especially noteworthy that expiratory motion is absent The percussion note is ringing and breath and voice sounds are reduced The trachea and heart will be shifted only in case of considerable pneumothorax Fluoroscopy and x ray reveal various degrees of pulmonary compression

The immediate treatment is bed rest plus relief of pain which frequently may require morphine (15 mg) though codeine (30 to 60 mg) or Demerol (100 mg) may be sufficient Some authorities start oxygen at once but this would not appear to be necessary unless cyanosis is present The reabsorption of nitrogen from the pleural cavity which results from inhalation of 100 per cent oxygen does not seem a sufficient justification for its use in the absence of cyanosis On occasion if the

white cells almost solely lymphocytes and with a number of red cells as well Such a fluid is produced most commonly by neoplastic or embolic disease

On rare occasions the inflammatory fluid usually a sequel of embolic or neoplastic disease or of mild trauma to the pleura may contain from 60 to 90 per cent eosinophils Experimental study suggests that such cells are late responses to the presence of blood certainly it is usually fruitless to search for a recognizable allergic or parasitic explanation

Noninflammatory Pleural Fluids On the basis of the strict definition set forth true transudate is to be found only in states of salt and water retention such as congestive heart failure or the nephrotic stage of renal diseases The only exception is the fluid *ex vacuo* which accumulates in a pleural sac when the intrapleural pressure reaches −20 cm H_2O and overcomes the oncotic pressure

Chylothorax a condition encountered very rarely is usually associated with neoplastic erosion of the thoracic duct The fluid aspirated is characteristically milky in appearance and shows microscopically great numbers of fat droplets

Huge numbers of cholesterol crystals may be found in pleural fluid which has lain neglected in the chest for many months The fluid is grossly quite cloudy and looks like white or cream colored pus Hardly any cells are to be found and most other studies are fruitless

The discovery of bile in pleural fluid is of very great importance and is a common finding in thoracoabdominal trauma Such fluid indicates a free communication between the liver parenchyma and the pleural cavity and calls for surgical measures

Physical examination of the chest in patients with noninflammatory fluid presents the same findings with the exception of tenderness that are obtained over inflammatory fluids The radiologic findings are also the same

In fluids which have been present for a very long time however there may be reduction in size of the chest and a shift of the mediastinum to the side of fluid The explanation of these observations is that the lung underneath the fluid has been markedly collapsed and has never been able to re expand even though a portion of fluid has been reabsorbed The findings are thus the same as those in fibrothorax the sole difference being the discovery of loculated fluid

Treatment of Pleural Effusion Attempt at aspiration is indicated whenever pleural fluid is suspected The three main objectives are (1) mechanical relief of dyspnea (2) reexpansion of lung and obliteration of pleural space in all inflammatory pleurisy (3) acquisition of information from the fluid and from complete visualization of the lung All three purposes demand complete emptying of the pleural sac Repeated taps are perfectly justifiable so long as they serve any one of the above purposes So long as one follows a careful technique with regard to asepsis is generous with local anesthetic agent and keeps the aspirating system closed to the atmosphere one need have little fear of accidents Lung laceration and the production of pneumothorax may be avoided by the use of an anchoring clamp on the needle advancement of which should be stopped the instant the pleura is traversed

Sterile tubes for bacteriologic study should be available and some should contain an anticoagulant since clotting may set in very rapidly and completely ruin the specimen for detailed study

The minimum examination of pleural fluid should include one s own gross observations as to color odor viscosity and turbidity specific gravity a total and differential cell count and protein determination In addition cultures for tubercle bacilli fungi or anaerobic organisms guinea pig inoculation and Papanicolaou or other cytologic study may be necessary When tuberculous pleurisy with effusion is to be considered a sugar determination may be of assistance Such effusions are said to contain relatively less sugar (compared to the blood) than do other fluids Personal experience suggests that the study is of very limited value

The differential diagnosis may remain in doubt after all these procedures If the fluid is inflammatory and not otherwise explained the tendency in the past has been to regard such effusions as tuberculous till proved not to be In some cases much time and trouble may be saved for the patient with obscure effusions if decision on pleural biopsy is reached early

The treatment of pleurisy is the treatment of the fundamental disease for which unfortunately in many instances there is no specific therapy In such cases the problem resolves into one of relieving the patient s dyspnea by repeated taps When the etiologic agent is bacterial however the effusion is commonly treated by aspiration of the pleural contents and administration of antibiotics Direct injection of antibiotics into the pleural cavity apparently is not always desirable though in heavily contaminated pleurae the injection of 200 000 units of penicillin daily or every other day may be of some assistance In early pneumonias with serofibrinous effusion results are usually highly satisfactory

If fluid develops in the face of inadequate or inappropriate antibiotic therapy the course is likely to be much more prolonged and the results are less satisfactory In such cases loculation develops large masses of fibrin are laid down and aspiration usually is productive of only a few milliliters of fluid Under these circumstances the choice lies between

result of congestive heart failure (see Chaps 14 26) Congenital anomalies of the heart and great vessels rarely if ever produce direct effects upon the pulmonary parenchyma although aneurysm of the aorta frequently may produce bronchial obstruction with consequent diffuse infiltration and suppuration (see below) In extensive roentgenographic surveys aneurysm of the pulmonary artery is encountered occasionally the condition is of interest chiefly from the fact that it must be differentiated from aortic aneurysm carcinoma of the bronchus and hilar adenopathies

PULMONARY EMBOLISM AND INFARCTION

In this discussion embolization will be used to refer to the passage through the circulation of any type of material foreign to the normal content of the vessels The commoner materials are blood clot marrow fat or gases Occasionally as in wounds from missiles metallic foreign objects may enter the circulation and be carried centrally

Infarction refers to damage to the structure of the lung itself Hence it is possible for embolization to occur without infarction but not for infarction to take place without an embolus

Embolization of the pulmonary circulation with fat takes place frequently as a result of severe injury especially to the lower extremities pelvis and spine Embolization by clot is a common complication in patients recovering from surgical operations severe injury to the legs prolonged febrile illnesses and in patients with cardiac disease The commonest source is the veins of the calves but emboli may arise from the pelvic veins or in patients with atrial fibrillation from the right atrium Gas embolization of the pulmonary circuit undoubtedly occurs with some frequency during intravenous fluid administration in traumatic or surgical opening of vessels of the neck and as one aspect of caisson disease (see Chap 106) In the case of gas embolization the large pulmonary bed is usually able to accommodate considerable quantities of gas and aside from temporary breathlessness and a sense of oppression no serious damage occurs unless gas reaches the left side of the heart

Marrow fat and clot particles may be of any size from minute fragments to occlusive masses The symptoms depend largely on the size of the clot and perhaps on reflex changes produced in the pulmonary vascular bed In mild cases the patient may have episodes of dyspnea tachycardia and anxiety with retrosternal pain and sometimes with fleeting attacks of pleuritic pain for which no cause is evident The blood pressure may be quite variable with episodes of sudden fall corresponding to the occurrence of retrosternal pain or discomfort brief periods of a shocklike state may follow

Massive embolization may be preceded by such seemingly terminal symptoms or may take place without warning In severe embolization the patient who may previously have seemed quite well, suddenly experiences severe retrosternal pain becomes cyanotic and intensely dyspneic and develops vascular collapse Differentiation from occlusion of a coronary artery may be very difficult Death may occur within a few minutes If the patient survives the severe episode he may remain in a state of profound shock from which with appropriate treatment he may slowly recover If the treatment of pulmonary embolization is to be successful therapy must often be undertaken while the diagnosis is presumptive In some instances death takes place so rapidly and with so little warning that no therapy is possible If nonfatal shock occurs the treatment is like that of shock in association with coronary heart disease Results of attempts at embolectomy from the pulmonary artery have been such that the procedure is rarely undertaken Other treatment if the patient survives the acute episode is directed toward prevention of additional embolization if the site of origin can be identified and occluded from the main circulation

Pulmonary infarction is the pathologic change that may result from an embolus Castleman distinguishes true infarcts with necrosis from very similar changes of intense hemorrhage into tissue but without necrosis the latter he defines as *pseudoinfarcts* Clinically the conditions are not differentiable except when it is possible to discover radiographic rarefaction in the center of the opacified area

The infarcted area early presents grossly the appearance of red infarction and microscopically the appearance of necrosis Later the gross appearance is that of the so-called *white infarct* while still later it is possible that the most careful search of the lung will fail to show any residual damage as the complete dissection of the pulmonary arterial tree may show no evidence of clot or of recanalization

Infarction may succeed a clinical picture of embolism as described above or may (and more usually does) manifest itself as the sudden onset of severe pleuritic pain followed immediately by cough cyanosis and dyspnea and a little later by blood spitting On occasion there is a repetition of the attack, with pain in some other area of the same or the opposite side

Pleural pain is very common and usually quite severe If the pain has been at all striking or persistent the patient should be observed closely for evidence of pleural fluid

patient is in considerable distress and the pneumothorax is large and under positive pressure aspiration of air is indicated Although one may relieve a patient merely by syringe removal of gas the pneumothorax machine with its manometer is a more precise method It is preferable to remove only 200 to 300 ml of gas on each occasion and to remove it frequently rather than to attempt very extensive decompression since the rapid withdrawal of gas tends to reopen and perpetuate the pulmonary pleural communication In some few cases accumulation of gas is so rapid and distress so great that more heroic treatment is indicated In such cases a sterile 18 French urethral catheter may be inserted through the second anterior interspace and connected to a water trap Some prefer to treat all but the smallest pneumothorax in this manner Even in very severe cases this measure is usually followed by rapid reexpansion but in a rare instance the rupture may be so large as to require continuous suction by means of the Stedman pump In some few patients the recurrence of pneumothorax is so frequent and disabling as to call for surgical intervention which usually consists of the removal of the bulla bearing area if one is present and careful poudrage of the pleural surface Recurrences following such procedures have not been reported

Hemopneumothorax In about 1 out of 8 patients with spontaneous pneumothorax the onset of the collapse is associated with hemorrhage into the pleural cavity In these instances of spontaneous hemopneumothorax which supposedly occur on the same basis as simple pneumothorax the bleeding is assumed to result either from the avulsion of an adhesion from the substance of the rapidly collapsing lung or from accidental involvement of a pleural vessel in the rupture To the usual picture of spontaneous pneumothorax there are added in severe cases signs and symptoms suggesting acute blood loss In perhaps 10 per cent of hemopneumothoraxes bleeding may be extreme hence almost all the pathologic material available on spontaneous pneumothorax is derived from autopsies of individuals who bled to death

The physical findings are those of pneumothorax plus basal dullness X ray studies usually reveal rather extensive collapse with a fluid level on the affected side

The treatment indicated is that for spontaneous pneumothorax in general with additional management for shock and hemorrhage when indicated In the usual case bleeding decreases as the lung collapses farther down but sometimes it continues very actively necessitating transfusions As a rule blood and pleural fluid should be withdrawn within a day or two to prevent formation of clot or extensive deposition of fibrin on the visceral pleura In the more severely bleeding cases aspirations may be required almost hourly The medical management of such patients should be continued only long enough to prepare for open thoracotomy with direct control of bleeding

Tumors of the pleura are discussed on p 1400

236 DISEASES PRIMARILY OF CIRCULATORY ORIGIN

John S Chapman

Active hyperemia is the result of almost any kind of infection while passive hyperemia is the

result of congestive heart failure (see Chaps 14 228) Congenital anomalies of the heart and great vessels rarely if ever produce direct effects upon the pulmonary parenchyma although aneurysm of the aorta frequently may produce bronchial obstruction with consequent diffuse infiltration and suppuration (see below) In extensive roentgenographic surveys aneurysm of the pulmonary artery is encountered occasionally the condition is of interest chiefly from the fact that it must be differentiated from aortic aneurysm carcinoma of the bronchus and hilar adenopathies

PULMONARY EMBOLISM AND INFARCTION

In this discussion embolization will be used to refer to the passage through the circulation of any type of material foreign to the normal content of the vessels The commoner materials are blood clot marrow fat or gases Occasionally as in wounds from missiles metallic foreign objects may enter the circulation and be carried centrally

Infarction refers to damage to the structure of the lung itself Hence it is possible for embolization to occur without infarction but not for infarction to take place without an embolus

Embolization of the pulmonary circulation with fat takes place frequently as a result of severe injury especially to the lower extremities pelvis and spine Embolization by clot is a common complication in patients recovering from surgical operations severe injury to the legs prolonged febrile illnesses and in patients with cardiac disease The commonest source is the veins of the calves but emboli may arise from the pelvic veins or in patients with atrial fibrillation from the right atrium Gas embolization of the pulmonary circuit undoubtedly occurs with some frequency during intravenous fluid administration in traumatic or surgical opening of vessels of the neck and as one aspect of caisson disease (see Chap 106) In the case of gas embolization the large pulmonary bed is usually able to accommodate considerable quantities of gas and aside from temporary breathlessness and a sense of oppression no serious damage occurs unless gas reaches the left side of the heart

Marrow fat and clot particles may be of any size from minute fragments to occlusive masses The symptoms depend largely on the size of the clot and perhaps on reflex changes produced in the pulmonary vascular bed In mild cases the patient may have episodes of dyspnea tachycardia and anxiety with retrosternal pain and sometimes with fleeting attacks of pleuritic pain for which no cause is evident The blood pressure may be quite variable with episodes of sudden fall corresponding to the occurrence of retrosternal pain or discomfort brief periods of a shocklike state may follow

Massive embolization may be preceded by such seemingly terminal symptoms or may take place without warning In severe embolization the patient who may previously have seemed quite well suddenly experiences severe retrosternal pain becomes cyanotic and intensely dyspneic and develops vascular collapse Differentiation from occlusion of a coronary artery may be very difficult Death may occur within a few minutes If the patient survives the severe episode he may remain in a state of profound shock from which with appropriate treatment he may slowly recover If the treatment of pulmonary embolization is to be successful therapy must often be undertaken while the diagnosis is presumptive In some instances death takes place so rapidly and with so little warning that no therapy is possible If nonfatal shock occurs the treatment is like that of shock in association with coronary heart disease Results of attempts at embolectomy from the pulmonary artery have been such that the procedure is rarely undertaken Other treatment if the patient survives the acute episode is directed toward prevention of additional embolization if the site of origin can be identified and occluded from the main circulation

Pulmonary infarction is the pathologic change that may result from an embolus Castleman distinguishes true infarcts with necrosis from very similar changes of intense hemorrhage into tissue but without necrosis the latter he defines as *pseudo-infarcts* Clinically the conditions are not differentiable except when it is possible to discover radiographic rarefaction in the center of the opacified area

The infarcted area early presents grossly the appearance of red infarction and microscopically the appearance of necrosis Later the gross appearance is that of the so-called *white infarct* while still later it is possible that the most careful search of the lung will fail to show any residual damage as the complete dissection of the pulmonary arterial tree may show no evidence of clot or of recanalization

Infarction may succeed a clinical picture of embolism as described above or may (and more usually does) manifest itself as the sudden onset of severe pleuritic pain followed immediately by cough cyanosis and dyspnea and a little later by blood spitting On occasion there is a repetition of the attack with pain in some other area of the same or the opposite side

Pleural pain is very common and usually quite severe If the pain has been at all striking or persistent the patient should be observed closely for evidence of pleural fluid

Hemoptysis varies in amount but is usually not over 100 ml on any occasion Frequently it is much less The first blood expectorated is usually bright red and not unlike brick dust sputum After a day or two the color of the blood gradually changes to dark red or to brownish black or may consist of small dark clots The duration of blood spitting may be for several days depending upon the size and number of infarcts Hemoptysis of any type however occurs in only about 50 per cent of all cases

The temperature rises within a matter of hours after the infarction The level of pyrexia frequently is not very high rarely exceeding 101 5 F and often not above 100 F The duration regardless of treatment with antimicrobial agents usually is 4 to 5 days with defervescence by lysis unless there is complicating pleural effusion or repeated infarction or unless the emboli are mycotic and part of a picture of severe generalized infection

Physical findings on examination of the chest of patients with pulmonary infarction are variable In the case of quite large infarcts one encounters dullness bronchial breath sounds increased voice sounds and numerous medium moist rales In other cases particularly where there are numerous small infarcts there may be suppression of the voice and breath sounds with rales or occasionally large rhonchi In still others if the infarcts are small and not numerous discovery upon physical examination is unlikely If effusion into the pleural cavity occurs the signs are those of any pleurisy with effusion flatness absence of the breath and voice sounds and diminished fremitus

When suspicion of pulmonary infarction exists careful examination of the legs may lead to the establishment of correct diagnosis (see below)

Leukocytosis as a rule is not high the count rarely passing 12 000 to 14 000 and left shift is only moderate Icterus may be present if hepatic function is impaired but in other cases one can find confirmation of the suspected infarction in elevated urine urobilinogen When fluid can be aspirated sterile blood fluid of fairly high specific gravity (1 014 to 1 018) with a relative paucity of white cells affords good confirmation of one s suspicion

The electrocardiographic finding of acute cor pulmonale with typical S_1–Q_3 configuration is rather unusual and among cardiac patients may be entirely concealed by other abnormalities

The x ray findings in infarction of the lung are by no means so simple as the classic description of a wedge shaped shadow with the base at the periphery An infarct may have almost any shape and rarely presents a triangular shadow in the normal posteroanterior projection The base of the infarct may be against any surface of the pleura including the diaphragmatic and the septal surfaces so that the normal chest film reveals any shape that may result from the passage of a plane through a cone A striking characteristic of the radiographic shadow is that almost always there is a clear zone of aerated lung between the peripheral density of the infarct and the hilum

If infarcts are multiple one may gain from the film a clue in the predilection of infarcts for the left lower lobe—a result of the comparatively straight course of the pulmonary artery to that portion of the lung

In successive films over a period of 5 to 10 days sometimes in much less time the original patchy infiltrations disappear and are replaced by irregular linear shadows which differ from plate atelectases in that they take various angles to the diaphragm rather than the horizontal lines of compression atelectasis

While smaller densities are usually of brief duration larger shadows especially if they are associated with congestive heart failure may persist for many weeks

In the rare case the center of the density undergoes rarefaction and the radiographic appearance is that of an abscess cavity with fairly thick walls The location is not that of the usual anaerobic abscess and air fluid level is not present Such shadows disappear almost as rapidly as do the non cavernous densities and leave no visible abnormality in the area of damage

The differential diagnosis of pulmonary infarction varies chiefly with the type of x ray shadow encountered If the shadow is large and single bacterial pneumonia presents the chief problem A very careful history is of the utmost value Infarction is striking in the development of pleuritic pain *prior* to the onset of fever whereas in pneumonia fever cough and dyspnea usually precede the onset of chest pain Pneumonia may be associated with a chill infarction is not Fever and leukocytosis are not often as high in pulmonary infarction as in the usual case of pneumococcal pneumonia In infarction there is no response of fever to antimicrobial therapy and tachycardia anxiety shock and cyanosis may be out of proportion to the visible pulmonary disease

A smaller infiltration may resemble primary atypical pneumonia but will differ in that infarction practically always produces sharp pleuritic pain and some degree of polymorphonuclear leukocytosis whereas such changes should not occur in atypical pneumonia

Infarction with cavity formation differs from abscess in mode of onset in absence of previous history of loss of consciousness in absence of foul

or purulent sputum in failure to respond to anti microbial drugs and in persistence of sputum that is chiefly blood either fresh or hemolyzed

Multiple infarctions may be confused with bronchopneumonia especially when they occur as a result of heart failure extensive trauma or prolonged infectious disease The problem is even more difficult in the presence of congestive heart failure with edema fluid in the pleural sac since infarction then takes place without pain A rise of temperature and the presence of leukocytosis are common to both diseases In neither case may there be pro ductive cough The development of an elevated serum bilirubin irregular bouts of tachycardia not otherwise explained and the appearance of red and white blood cells in pleural fluid that is sterile are points in favor of pulmonary infarction Pulmonary infarction especially if multiple or repeated delays or prevents response to usual management of congestive failure

Infarcts resulting from *fat emboli* differ in no respect clinically or radiographically from thrombotic emboli They should be suspected in patients who have recently experienced serious trauma to the spine pelvis or lower extremities and in whom dyspnea pleuritic pain cyanosis or unexplained shock is present The suspicion may be confirmed by the discovery of free or phagocytized fat droplets in the sputum (best seen in wet mounts or with Sudan III stain) provided there has been no recent ingestion of fat or possible cause for lipid pneumonia Similar fat droplets are often present in the urine

Mycotic emboli produce multiple abscesses of the lung The patient is severely ill with usual evidence of severe sepsis in addition to which there is marked dyspnea pleuritic pain cyanosis and sometimes shock Chest films reveal multiple abscesses distributed at random throughout both lungs Blood cultures should be positive The usual source of septic emboli is a gravid uterus on which a mechanical attempt at abortion has been made Severely traumatized and heavily infected extremities may be an occasional source of infected emboli

Treatment The treatment of pulmonary infarction is the treatment of the phlebothrombosis or thrombophlebitis which produces it Although penicillin is frequently prescribed on the basis that it may prevent infection in the damaged lung there is no real evidence that the antibiotic is of value Whether the administration of anticoagulants has direct effect upon the infarct itself is moot the duration of x ray shadows of infarction is so variable that demonstration of such an effect would be most difficult Hemoptysis is not of sufficient moment to call for any special treatment other than reassurance Pleural effusions if present should be aspirated since they may be of diagnostic value and particularly since they contribute to dyspnea

In the special case of septic infarction antimicrobial drugs of course are imperative Their choice will depend upon the antibiotic susceptibility of organisms obtained from blood culture While awaiting these results the physician should administer penicillin intravenously in the amount of 20 million units daily with 4 Gm of a broad spectrum antibiotic such as tetracycline Oxygen and fluids are demanded If the patient can be brought into condition that permits there is absolute indication for ligation of the inferior vena cava

Late Results Although in most cases of pulmonary infarction no serious damage seems to result in a certain number of patients a large embolus in a major artery may remain *in situ* and undergo propagation in the pulmonary vascular bed while repeated embolization by small clots may produce progressive vascular disease In either case the end result will be increasing and pulmonary arterial pressure with eventual right heart failure and death (see cor pulmonale)

PULMONARY HEMOSIDEROSIS

On occasion in patients with mitral stenosis with long standing congestive heart failure the chest film may reveal well defined miliary nodulation which has been shown pathologically to be deposits of hemosiderin with associated pulmonary fibrosis Whether lung function is significantly impaired by these changes is not known since pulmonary congestion from the stenosis itself as well as pulmonary arteriolar disease plays so large a part in the production of dyspnea in these patients

237 DISEASES OF THE BRONCHI AND PULMONARY PARENCHYMA

John S Chapman

Certain of the more important specific infections of the lungs such as tuberculosis and the pneumonias have been discussed in preceding chapters For the sake of convenience the various neoplastic disorders of the respiratory system are considered in Chap 238 The discussion to follow will be concerned with the remaining disorders of the lungs and bronchi

ACUTE BRONCHITIS

Bronchitis may occur as a primary disease may develop in the course of other specific infectious diseases or may occur as a result of distal pulmonary involvement Commonly the distribution is diffuse but occasionally it is localized

Among the specific infectious diseases in which bronchitis is a prominent phenomenon are pertussis influenza typhoid fever and the exanthemas but bronchial irritation has also been reported in malaria some of the rickettsial diseases and in those worm infestations marked by a pulmonary phase Localized bronchitis is found in the bronchus draining suppurative parenchymal disease and areas of tuberculosis or subjected to extrinsic pressure

In many individuals almost every invasion by the common cold results in a descending infection which eventually produces an acute inflammation of the trachea and bronchi The disease is usually mild and tends to run its course within one or two weeks

Such gases as were used in the First World War produced intense bronchial irritation which in severe cases went on to pneumonia or pulmonary edema Under industrial conditions exposure to these gases may develop on occasion from this standpoint the most important are ammonia chlorine sulfur dioxide hydrogen sulfide and under special conditions phosgene It is conceivable that severe exposure may result occasionally in emphysema

In *acute bronchitis* the complaints are those of cough expectoration at first of scanty mucus later of more abundant mucopurulent material and very commonly a sense of rawness located behind the sternum and extending somewhat to either side The patient states that cough is associated with tearing pain located in the same areas The temperature is variably elevated more commonly only mildly but occasionally to as much as 103 F

Physical examination reveals mild to severe acute illness in a patient with racking dry cough In the usual case there is injection and edema of the nasal and pharyngeal mucous membranes Unless the bronchitis is superimposed on some chronic disease the examination of the chest is noteworthy only for variable large rhonchi and occasional inspiratory fine wheezes

X ray of the lungs reveals no evidence of disease and laboratory studies commonly present the positive findings of moderately elevated white blood count with some increase in polymorphonuclears and a mild left shift Sputum usually contains a variety of common inhabitants of the respiratory tract with gram positive cocci in the great majority Other laboratory studies are of no value except for the exclusion of bronchitides associated with typhoid fever and the other specific infectious diseases

Treatment should consist primarily of bed rest Treatment is symptomatic Steam inhalation will control moderate cough but codeine may be required Salicylates are useful for fever or malaise

CHRONIC BRONCHITIS

In a certain percentage of patients cough and expectoration persist sometimes for many months In the early mornings the cough is usually productive but it frequently occurs during the night in paroxysmal form with little or no sputum Sometimes frank hemoptysis may occur but more usually the patient complains only of blood streaked sputum Pain is not a prominent feature in such illness and there is no fever weight loss or decline in strength or vigor Of this group a large number have additional complaints referable to the nose or paranasal sinuses and postnasal drip is very common Mouth breathing may contribute to difficulties while persistent cough itself adds to bronchial irritation and edema A personal or familial history of allergy is usually lacking but the history of smoking is almost always present

Examination usually reveals a somewhat hyperemic but frequently crusted and dry nasal mucosa The pharynx either is of a "granular" or lymphoid character or presents the appearance of unusual dry redness The physical examination of the lungs presents nothing more than occasional rhonchi or a rare inspiratory wheeze No changes in the circulatory status are evident and there is no clubbing of the fingers

The chest film is normal in appearance and the blood count not remarkable Sputum as a rule is rather scanty and is composed of tenacious mucus in which there are relatively few cells or organisms Films of the sinuses frequently present no evidence of disease

The differential diagnosis in such individuals is of considerable importance since neither the negative chest film nor physical examination can be considered sufficient to exclude more serious disease In a certain number of cases tuberculosis first manifests itself in such fashion so that the sputum must be carefully searched and cultured to exclude that disease Carcinoma of the bronchus and bronchiectasis constitute other possibilities that need to be absolutely excluded therefore these patients may often require bronchoscopy and bronchography before one can conscientiously reassure them completely

At bronchoscopy the mucosa of the trachea and bronchi appears usually red and somewhat redundant and has a tendency to stick to the instrument Coughing is usually marked during bronchoscopy of such patients and it may be observed that the walls of the trachea and bronchi almost collapse shut during cough Secretions are usually very scanty Rarely is it possible to find ulceration or definite granulation Biopsy if taken reveals only chronic inflammation

Bronchograms commonly reveal a loss of finer branches with much beading (due to droplets of mucus) along the larger branches Mild degrees of cylindric bronchiectasis sometimes are observed

The first step in treatment consists of the exclusion of any possible irritants Tobacco is interdicted If the patient s occupation brings him into contact with dust fumes gases or paint in many cases he will never get rid of his cough until his environment has been changed He should avoid public gatherings and should attempt to maintain both his house and his place of work as thermo stable as is possible Usually some degree of humidification of the air particularly in winter is required Moderate exercise in the open has seemed of some value as has much outdoor activity in the sun during the summer

For immediate symptoms a codeine-containing cough syrup and a steam kettle afford about as much relief as can be obtained Particularly when sputum is scanty and tenacious the addition of potassium iodide or ammonium chloride may be of some benefit In certain patients the antihistaminic drugs may offer additional relief These things failing one may try a large number of expedients usually with little success Occasionally a patient recovers entirely following diagnostic bronchoscopy Not infrequently one may have to prescribe residence in a climate warm sunny and dry throughout the year

PULMONARY FIBROSIS AND EMPHYSEMA

Under this combined term are grouped a large number of somewhat related conditions One or the other element of fibrosis or of emphysema may predominate but one element is practically never found without some trace of the other The clinical disease may be defined as a chronic respiratory process characterized by some type of respiratory insufficiency (ventilatory or alveolocapillary) and marked by various degrees of overdistention of the alveoli interspersed among areas of fibrosis

Classification

Classification of these diseases on a basis of pathologic and physiologic differences seems sound Three types are recognized The first is diffuse obstructive emphysema with characteristic overdistention and bulla formation The second perifocal emphysema develops about foci of fibrosis and is associated with comparatively mild overdistention The third variety is senile emphysema

Any of these types except senile emphysema may be either localized or generalized Obstructive emphysema may be confined to a single segment or it may involve homologous segments on the two sides with marked compression of the remaining segments

Pathology *Bullous Emphysema* Grossly the lungs are greatly overdistended rather pale noncollapsible and feathery to the touch Over the surface but particularly along the margins large air containing vesicles are frequent On section numerous air vesicles ranging in size from 2 mm to several centimeters in diameter are seen throughout the entire lung substance Very little normally crepitating tissue can be found

The histologic picture is that of flattening of alveolar septa rupture of alveoli into each other obliteration of blood and lymph channels and in the interstitial tissue a round cell infiltration with areas of true hyaline fibrous tissue The bronchioles and bronchi usually reveal thickening of the mucous membrane with submucosal round cell and polymorphonuclear infiltration

Small Lung or Senile Emphysema The lungs usually fail to collapse when the chest is opened and occasionally bullae are seen along the margins The lungs are flabby and distinctly less elastic than normal On section vesicle formation is minor and relatively few bullae are seen

Histologic examination is likely to show very minor changes

Pathogenesis Various explanations of diffuse obstructive emphysema have been offered By certain writers it is considered to be the effect of atrophy resulting from vascular changes by others to result from some type of congenital defect in supporting and elastic tissues by the majority to develop as a consequence of chronic bronchitis

Once the process has begun the steps in its progression are obvious Submucosal swelling and

readily demonstrable bronchospasm result in trapping of air since bronchiolar lumens narrow during expiration and diseased branches may close entirely Alveoli overdistend and eventually rupture into each other Since even the major bronchi collapse during hard cough stasis of secretions develops and adds to the bronchitis present Rapid changes in pressure as a result of cough tend further to overinflate distended areas which in turn compress adjacent healthy alveoli

Perifocal emphysema is thought to develop about small areas of nodular fibrosis such as a healing nodule of tuberculosis If the disease is generalized the exciting cause may be some diffuse disease such as healed sarcoidosis Bronchitis is not a factor but the condition seems to result in distortion of respiratory bronchioles Ventilatory defect is chiefly of the restrictive type

The pathogenesis of small lung emphysema is thought to be mainly the process of aging with gradual degeneration of the elastic fibrils in the interstitial tissue of the lung Another important factor in the production of this disease is the calcification of the costal cartilages and variable ankylosis about the heads of the ribs so that thoracic wall motion is greatly reduced Postural changes that go with age tend to inhibit the free motion of the diaphragm

Pathologic Physiology *Bullous Emphysema* If one bears in mind that expiratory obstruction is fundamental in the large lung type of emphysema the physiologic changes that result are obvious The first effect is retention of gas in the lungs In physiologic terms this means that the functional residual volume is greatly increased Most of this increase is in the form of true residual volume for usually expiratory reserve volumes are reduced below normal values The effect of an increase in functional residual volume is to displace all other volumes so that the patient comes to breathe nearer and nearer to the top of his pulmonary capacity Tidal air nearly always is increased and the inspiratory capacity can only be markedly decreased since the total lung volume is almost constant for the same individual if there is no progressive fibrosis

If functional residual volume is increased and expiration is obstructed a necessary consequence is retention of carbon dioxide The first effect of increased concentrations of this gas will be a drive toward more rapid and deeper respiration and therefore a larger tidal air volume But because of the degree of bronchospasm in different areas of the lung diffusion of gases is inefficient and trapping in first one area and then another takes place readily Thus another of the major factors in the physiology of emphysema is poor mixing of gases As the carbon dioxide tension of alveolar air (and hence of arterial blood) rises the respiratory center tends to become relatively refractory to the carbon dioxide stimulus to respiration and the patient comes to breathe largely from the hypoxic stimulus

Carbon dioxide retention sets in motion a series of chemical changes in the blood The immediate effect is respiratory acidosis which the body at once undertakes to compensate Compensated gaseous acidosis is achieved by increasing the alkali reserve (carbon dioxide–combining power) which is accomplished by excretion of chloride The chemical picture of the individual with advanced emphysema is therefore one of decreased chlorides increased alkali reserve and—as long as the gaseous acidosis is compensated—a normal or but very slightly lowered pH Other chemical aspects of the disease are elevated carbon dioxide tension and content of alveolar gas and arterial blood with near normal oxygen content and tension except under conditions of exercise or advanced disease when unsaturation may occur

From the ventilatory standpoint the picture in sum is that of increased tidal volume with hyperventilation reduced expiratory reserve volume poor mixing trapping of air with delayed emptying a moderately reduced vital capacity and a markedly reduced maximal breathing capacity and respiratory reserve Expiratory flow rate is slow and lung compliance reduced

Circulatory effects are to be expected if the respiratory system is so severely affected but a good many patients die of emphysema without ever having manifested circulatory failure When the circulation is involved however several factors play a part If hypoxia is fairly marked and persistent secondary polycythemia may develop with increased hematocrit and blood viscosity If hypoxic spasm or obliteration of the pulmonary capillary bed develops pulmonary hypertension is certain to result and consequently right ventricular dilatation and hypertrophy with ultimate right heart failure

A secondary effect on the circulation results from the prolonged forcible expiration The intrathoracic pressure is raised and blood is held out of the thorax When inspiration commences a large increment of blood enters fills the right atrium and ventricle and is then ejected into the pulmonary circuit The effect is of phasic alteration in cardiac output manifest peripherally as a paradoxic pulse and centrally as cyclic variation in pressures

The mechanical work of respiration in patients with obstructive emphysema is much increased since expiration has to be aided by active contraction of accessory respiratory muscle The problem of fatigue should be borne in mind when these patients are placed under stress Decreased clim

ination of carbon dioxide with decompensated gaseous acidosis may result from administration of oxygen or anesthetic agents

Perifocal Emphysema If the disease is limited in extent there is likely to be no significant physiologic change If the process is extensive ventilatory insufficiency may be of the restrictive type Trapping is usually not sufficient to result in carbon dioxide retention but fibrosis may affect the capillary bed either to result in physiologic shunts obstruction of the vascular bed or diffusional defect The major chemical changes will be reduction of arterial oxygen content pressure and saturation and if hyperventilation occurs decreased arterial carbon dioxide with potential elevation of pH

Small Lung Emphysema The major findings in this disease are those of reduced vital capacity maximal breathing capacity and breathing reserve Residual volume and functional residual volume may be mildly to moderately increased Since bronchial obstruction is not a significant feature of the disease there is no carbon dioxide retention and consequently none of the secondary chemical alterations Secondary circulatory effects are usually absent

Contributing Factors Bullous emphysema is predominantly a disease of males In a fairly large series the age at onset was frequently in the late thirties or early forties and in a significant number the disease was stated to have followed a specific attack of respiratory infection Cases were equally divided among people of sedentary occupation and those who performed moderate to heavy manual labor Many patients gave histories suggesting unusual vigor in their earlier lives and almost all had been heavy smokers Nasal disease under various appellations was conspicuous in the history of over half

Senile emphysema appears more equally in the sexes although again there is male preponderance Aging appears to be the only factor of great importance though posture and a previously sedentary life may play a small part in the inefficiency of ventilation and the fixation of the thoracic cage

It is very important to point out that the patient s age is not sufficient grounds for attributing breathing difficulty to senile emphysema Quite elderly men may have bullous emphysema and occasionally younger individuals develop the senile type

Finally emphysema must be understood to occur either alone or as a complication of other pulmonary diseases True pathologic emphysema may develop in association with tuberculosis pneumoconioses bronchiectasis and chronic abscess Equally any of these diseases as well as carcinoma may develop in any individual who already has bullous emphysema In such instances it is most important to determine that the condition present is emphysema rather than simple over distention a condition in which the lung or lobe is larger than normal but functions quite well without air trapping irregular mixing or carbon dioxide retention

Symptoms The first complaint is either of shortness of breath or of cough Shortness of breath is likely to be noticeable upon any exertion to be aggravated by changes in weather or by excitement and to be markedly increased by upper respiratory infection The patient is quite comfortable when recumbent but frequently states that he is unable to lie on either side Cough is usual and it may be nonproductive or moderately productive Paroxysms of cough particularly early in the morning are exceedingly troublesome and changes in posture nearly always result in difficult breathing and in increased cough Sputum is usually rather tough tenacious and mucoid but may be mucopurulent from time to time Not infrequently bloody streaks and small hemoptyses may be noted Chest pain particularly in the lower costal areas occurs rather often and is of a definitely pleuritic type Examination may reveal a fractured rib from cough

As the disease progresses it is usual for rather marked loss of weight to occur Patients may be so dyspneic as to be unable to eat with any comfort since swallowing demands inhibition of respiration Swelling of the feet and ankles indicates a rather late stage of the disease with onset of right heart failure

The symptoms of senile emphysema as a rule are quite mild and consist chiefly of shortness of breath upon exertion Cough is mild and other symptoms are usually absent except perhaps for some complaint of weakness and fatigue The symptoms of perifocal emphysema are shortness of breath and later those of cor pulmonale

Diagnosis *Physical Examination* Early emphysema may be so mild as to be detectable only by rather extensive pulmonary function tests The average patient with sufficient symptoms to call for medical aid will therefore be described The patient is usually in obvious respiratory distress and often can speak but a few words at a time There may be a trace of cyanosis about the lips and nails Neck veins frequently are engorged during the rather long expiration

Characteristically the chest is large and deep with elevation of the clavicles so that the neck appears unduly short High dorsal kyphosis *is nearly* always manifest The costal margins flare outward and the maximal respiratory excursion *is seen in* the midepigastrium where cardiac pulsation also is

visible and often quite forceful Chest wall motion is very limited and is restricted to a lifting upward and forward of the sternum Expiration is prolonged and is accompanied by obvious effort In certain patients the epigastrium bulges outward during expiration and retracts during inspiration a finding that indicates a marked incoordination of respiratory muscles as well as practically total lack of function of the diaphragm

Percussion produces a ringing hyperresonant note The heart margins are difficult to percuss and the diaphragm is very low Often there is no change in position of the diaphragm from inspiration to expiration

On auscultation the heart sounds are usually distant or inaudible If they can be heard P_2 is often much greater than A_2 and may be reduplicated Breath sounds are very distant throughout the chest except when emphysema is limited for example to the upper lobes in which case the breath sounds above are very distant while below breath sounds may be quite harsh When the sounds have sufficient volume to be followed throughout the phases of respiration it is noteworthy that they take on a distant bronchovesicular character due to the patient s obstructed expiration Adventitious sounds consist primarily of variable wheezes and rhonchi which may be heard during both phases of respiration It is characteristic that they are variable in size in time and in position Now and again one may hear along the lower borders of the axillae very fine crackling sounds similar to very fine moist rales These are thought to be the result of crepitus produced by the movement of vesicles across the pleura

Patients with senile emphysema present relative fixation of the chest poor motion of the somewhat depressed diaphragm but breath sounds that are usually fairly clear and possibly harsh Adventitious sounds are rarely heard and the physical examination of the heart is as satisfactory as in the normal individual

In perifocal emphysema only tachycardia hyperventilation and possibly cyanosis may be found

Roentgenographic Findings The ribs usually appear to be in an elevated and nearly horizontal position and the interspaces are widened The diaphragm can be seen at the level of the eleventh rib or just below it and characteristically the upper surface of the diaphragm appears to be scalloped with numerous arcs that are concave upward The mediastinum is usually in the normal position but the heart appears to be small because of the fact that the apex is rotated downward Roentgen signs of right ventricular enlargement or increase in size of the pulmonary outflow tract are seen only occasionally

The lung fields are remarkable for their radiolucency and for the absence of lung markings Occasionally one may see linear and patchy densities which represent areas of heavier fibrosis Sometimes it is possible to outline large bullae with very thin fibrous septums between adjacent ones If the fissure lines are visible they may be displaced somewhat from their normal positions depending upon the areas of maximal emphysema or fibrosis When emphysema is localized to a single lobe the other homolateral lobe may appear to be much reduced in size and to present the roentgenographic appearance of partial collapse Markedly asymmetrical emphysema may displace the heart and mediastinum to the opposite side and occasionally may simulate spontaneous pneumothorax very closely

It is noteworthy that in the lateral films the heart appears to be separated from the sternum by a considerable distance which is occupied by the bullous margins of the lungs Fluoroscopic examination presents a diaphragm that may move through not more than 2 to 3 cm from maximal inspiration to maximal expiration If the ascent is greater than that it is usually accomplished very slowly Lightening and darkening of the lung field as a whole does not occur during respiration but one may see portions of the lung darken with expiration while adjacent areas remain quite lucent This discovery is a certain sign of air trapping as is a shift of mediastinum out of the midline during expiration

Senile emphysema is not regularly to be diagnosed from the x ray film Fluoroscopy reveals no evidence of air trapping Relatively poor motion of the chest wall and diaphragm may be evident from this examination however

Perifocal emphysema may be recognizable only by the presence of nodulation or fine fibrosis In many instances it cannot be diagnosed radiographically

Laboratory The usual laboratory studies are of little value unless there is question of secondary polycythemia or some complicating disease Sputum smears and cultures present a variety of organisms none of which can be regarded as significant Minimal chemical study should include chlorides and carbon dioxide–combining power

The circulation time and venous pressure should be determined if there is any question of associated heart disease

Treatment Under ideal conditions the patient should live in a warm dry climate in which exposure to dust irritants pollens and smoke should be minimal if not completely absent His occupation should preferably be sedentary and he should be protected against emotional stress and any but the mildest exertion If his occupation permits he

should take a rest after lunch and have more than the usual amount of rest at night *During epidemics* of respiratory disease he should avoid all public gatherings *Tobacco should be completely forbidden* though occasional and moderate use of alcohol *is permissible If he is underweight* several small feedings of high caloric value rather than three *regular meals may be advised He must be made* to understand that his condition is not reversible but that *its progression* can be arrested and that his symptoms can be improved Some attention to the condition of the nasal mucosa may be indicated but extensive nasal surgery should be avoided if possible Frequently antihistamines suffice to control a chronic nasal irritation if cessation of smoking does not

Three general purposes are undertaken in the treatment of diffuse obstructive emphysema promotion of bronchial drainage control of bronchial infection and improvement in bronchospasm and bronchial *obstruction In practice* measures taken for one of these purposes to some extent aid in the others

Bronchodilators Parenteral adrenalin has little place except when emphysema is associated with true bronchial asthma Aminophylline is very useful This drug may be administered in doses of 0 25 to 0.5 Gm intravenously over a period of at least 5 *min as often as every 4 hr orally in maintenance* therapy in doses of 0 2 to 0 3 Gm either alone or in *combination with other drugs four times daily or* rectally as 0 3 to 0 5 Gm in solution introduced through a catheter well up in the rectum This method of rectal administration produces rapid relief and avoids the irritation produced by suppositories

Ephedrine as 15 to 24 mg tablets is convenient for the patient to carry about with him and gives some relief during working hours when he may wish not to use a nebulized bronchodilator This drug may be used as such or in combination with aminophylline in the form of many useful proprietary tablets or capsules

Nebulized bronchodilators are solutions of various derivatives of epinephrine or similar compounds *Those most in favor include* Isuprel Aerolone compound and Asthmanefrin They may be administered through *any nebulizer capable of producing* a finely divided aerosol Much better results follow inhalation of these mists after the patient makes a strong exhalation rather than as he attempts strong inspiratory efforts Such therapy may be used as often as once an hour

Antibiotic Therapy The interest in nebulized antibiotics has largely subsided If the sputum is purulent and voluminous repeated short (5 to 7 day) periods of penicillin treatment are quite beneficial The usual dose is 300 000 units daily For *prophylaxis Bicillin 1 million units monthly may* be tried but is of questionable value

In some patients maintenance protective therapy with a broad spectrum antibiotic 250 mg daily *throughout the season of respiratory infection* may be of a little value

Organisms identified from sputum cultures are extremely variable What part some of them play in the bronchitis associated with emphysema is not evident Far numbers of them are insusceptible to ordinary antibiotics and probably can be ignored in many instances *Candida* and unidentifiable molds have been noted they are of interest only by virtue of the fact that under broad spectrum antibiotic therapy the yeasts may overgrow the usual flora and give rise to major difficulty themselves

Vaccines seem to have little or no effect in average cases A very rare patient may show some improvement on vaccine treatment In the opinion of most writers stock vaccines are likely to be fully as effective as autogenous preparations

Bronchial Drainage Postural drainage of the kind usually prescribed in bronchiectasis is of no value unless there are areas of active infection such as associated pneumonia Patients with emphysema *may be unable to tolerate* positioning Regular rest and sleep prone on an inclined plane *headdown at about 15 is helpful if the patient* can tolerate the position The shift upward of abdominal contents *raises the diaphragm and may* over a time result in some improvement in its muscular tone and power

Expectorants occupy a very uncertain place in promotion of bronchial drainage One of the major features of the disease is tenacious and bubbly sputum Saturated solution of potassium iodide 10 to 15 drops four times daily may be worth trying Enteric coated tablets of ammonium chloride are usually of no avail since disintegration of the tablets in the bowel is very uncertain Smaller amounts of ammonium chloride in solution are fully as effective

Much *interest has developed* in the use of detergents as means of liquefying secretions and lowering *surface tension Although some* writers have found no significant advantage in the use of such materials when it is *desired to try them it is usual* either to utilize a dense mist in a tent or to combine a bronchodilator with a detergent 1 4 *and* to nebulize by some mechanical source of pressure 10 ml of this mixture as often as every 3 hr The patient during the process of inhaling the mixture should make strong expiratory efforts rather than efforts at deep inspiration The use of vaporized water either as steam or as cold vapor may be of some advantage

visible and often quite forceful Chest wall motion is very limited and is restricted to a lifting upward and forward of the sternum Expiration is prolonged and is accompanied by obvious effort In certain patients the epigastrium bulges outward during expiration and retracts during inspiration a finding that indicates a marked incoordination of respiratory muscles as well as practically total lack of function of the diaphragm

Percussion produces a ringing hyperresonant note The heart margins are difficult to percuss and the diaphragm is very low Often there is no change in position of the diaphragm from inspiration to expiration

On auscultation the heart sounds are usually distant or inaudible If they can be heard P_2 is often much greater than A_2 and may be reduplicated Breath sounds are very distant throughout the chest except when emphysema is limited for example to the upper lobes in which case the breath sounds above are very distant while below breath sounds may be quite harsh When the sounds have sufficient volume to be followed throughout the phases of respiration it is noteworthy that they take on a distant bronchovesicular character due to the patient s obstructed expiration Adventitious sounds consist primarily of variable wheezes and rhonchi which may be heard during both phases of respiration It is characteristic that they are variable in size in time and in position Now and again one may hear along the lower borders of the axillae very fine crackling sounds similar to very fine moist rales These are thought to be the result of crepitus produced by the movement of vesicles across the pleura

Patients with senile emphysema present relative fixation of the chest poor motion of the somewhat depressed diaphragm but breath sounds that are usually fairly clear and possibly harsh Adventitious sounds are rarely heard and the physical examination of the heart is as satisfactory as in the normal individual

In perifocal emphysema only tachycardia hyperventilation and possibly cyanosis may be found

Roentgenographic Findings The ribs usually appear to be in an elevated and nearly horizontal position and the interspaces are widened The diaphragm can be seen at the level of the eleventh rib or just below it and characteristically the upper surface of the diaphragm appears to be scalloped with numerous arcs that are concave upward The mediastinum is usually in the normal position but the heart appears to be small because of the fact that the apex is rotated downward Roentgen signs of right ventricular enlargement or increase in size of the pulmonary outflow tract are seen only occasionally

The lung fields are remarkable for their radiolucency and for the absence of lung markings Occasionally one may see linear and patchy densities which represent areas of heavier fibrosis Sometimes it is possible to outline large bullae with very thin fibrous septums between adjacent ones If the fissure lines are visible they may be displaced somewhat from their normal positions depending upon the areas of maximal emphysema or fibrosis When emphysema is localized to a single lobe the other homolateral lobe may appear to be much reduced in size and to present the roentgenographic appearance of partial collapse Markedly asymmetrical emphysema may displace the heart and mediastinum to the opposite side and occasionally may simulate spontaneous pneumothorax very closely

It is noteworthy that in the lateral films the heart appears to be separated from the sternum by a considerable distance which is occupied by the bullous margins of the lungs Fluoroscopic examination presents a diaphragm that may move through not more than 2 to 3 cm from maximal inspiration to maximal expiration If the ascent is greater than that it is usually accomplished very slowly Lightening and darkening of the lung field as a whole does not occur during respiration but one may see portions of the lung darken with expiration while adjacent areas remain quite lucent This discovery is a certain sign of air trapping as is a shift of mediastinum out of the midline during expiration

Senile emphysema is not regularly to be diagnosed from the x ray film Fluoroscopy reveals no evidence of air trapping Relatively poor motion of the chest wall and diaphragm may be evident from this examination however

Perifocal emphysema may be recognizable only by the presence of nodulation or fine fibrosis In many instances it cannot be diagnosed radiographically

The circulation time and venous pressure should be determined if there is any question of associated heart disease

Treatment Under ideal conditions the patient should live in a warm dry climate in which exposure to dust irritants pollens and smoke should be minimal if not completely absent His occupation should preferably be sedentary and he should be protected against emotional stress and any but the mildest exertion If his occupation permits he

tions Under conditions of bronchiectasis quite large communicating shunts may develop between pulmonary and bronchial arteries Immediately surrounding the saccules a polymorphonuclear infiltration is visible at some distance slides reveal round cell infiltration and young fibroblasts as well as much old hyalinized fibrous tissue

Since bronchi are much more easily obstructed when they are of small lumen the onset of bronchiectasis is often in infancy or childhood The aspiration of foreign bodies bronchopneumonia and bronchial occlusion associated with primary tuberculosis are frequently precipitating causes Occasionally the disease results from postoperative pneumonia or other bronchial obstruction in later life

There is commonly a *history* of repeated pneumonic episodes frequent colds general decline in health and strength intermittent low grade fever with sweating and above all persistent cough with expectoration One common feature of the history almost diagnostic in itself is the statement that cough develops upon lying down The sputum is described as abundant yellowish sometimes chunky and hard but by no means universally is foul Hemoptysis is quite frequent and at times may be severe Pleuritic chest pain often develops with each fresh infection but is usually not very severe

Physical Examination The patient often appears chronically ill In characteristic cases over the area of disease the examiner encounters mild lag dullness diminished breath and voice sounds and considerable numbers of variably sized moist rales In the rare instances of disease of the upper lobe only the sole physical sign may consist of moderate impairment of the percussion note In bronchiectasis limited to the middle lobe if much shrinkage of the diseased lobe has occurred there may be no physical signs at all The distribution of physical signs is usually lobar or segmental in character Clubbing of the fingers is usually pronounced

Roentgenogram of the chest sometimes appears entirely normal either because there is very little fibrosis or pneumonia or occasionally—and this is particularly true on the left—because the bronchiectatic lobe is so completely contracted as not to be visible in the routine projection In more characteristic instances heavy linear stranding is to be seen radiating downward and laterally from the hilum in a few cases the affected lobes may appear almost solid

Laboratory work is of little diagnostic advantage other than in the exclusion of tuberculosis The sputum characteristically purulent does not often settle out in the classic three layered form On slide and culture other than anaerobes no significant organisms . . .

The bronchoscope may reveal somewhat dilated and displaced orifices of the lower lobe with evidence of chronic inflammation and with abundant purulent secretion Bronchograms which should be used only for diagnosis and mapping should show complete outlining of the major branches of both lower lobes the middle lobe the lingular segment of the left upper and some of the branches of the right upper Several views are necessary for complete study including posteroanterior and lateral upon filling the first side and both oblique views The amount of oil used in filling both sides should not exceed 15 to 20 ml but it is preferable to study only one side at a time

The basic treatment is surgical extirpation of the diseased areas a procedure that can now be carried out with a mortality of not over 2 per cent Unfortunately either because of the extent or distribution of the disease or because of associated emphysema extrapulmonary disease or age a certain group of patients has to be classified as inoperable and treated medically For these patients the most that can be accomplished is amelioration of symptoms and prolongation of life

Postural drainage is the most important single measure in the management of inoperable bronchiectasis Four or five times daily and for 10 to 15 min at a time the patient should adopt the position in which experience shows he will have most profuse drainage and make persistent coughing and chest squeezing efforts Oftentimes the patient in attempting to avoid this somewhat unpleasant part of his daily routine will state that he does not cough at all during the time he is in drainage position but does produce sputum after assuming a more natural one This argument should not deter the physician from insisting upon continuation of postural drainage Persistent regular use of the measure may often reduce sputum production by as much as 75 to 80 per cent and commonly changes a putrid pus to an odorless one An additional aid is elevation of the foot of the bed so that gravitational drainage may take place through the night The inhalation of digestive enzymes (pancreatic dornase and trypsin) may assist in liquefaction and drainage but may lead to untoward reactions

Other than these measures those general rules set out for patients with chronic bronchitis are indicated In addition if the bronchiectatic patient s strength is at all depleted he should be ordered to rest 1 hr after lunch and to secure 9 or 10 hr of rest at night All patients should receive penicillin parenterally at the first sign of fresh infection The use of Bicillin once monthly on a prophylactic basis is of considerable advantage Other antibiotics may be of use in patients who are sensi... or who have organisms resistant to penicillin

Other methods of bronchial drainage will be discussed under the subject of acute respiratory insufficiency

Mechanical Measures The fundamental problem of course is to produce an easier and more effective expiration

Pneumoperitoneum may be given for the purpose of elevating the diaphragm reducing the resting lung volume and aiding in the evacuation of secretion In perhaps half the patients there appears to be slight to moderate short term benefit from this procedure Abdominal binders of various types have been tried over a considerable period of time They may be used alone or in conjunction with pneumoperitoneum but on the whole patients tolerate them poorly and eventually discard them

Breathing exercises are widely used If the patient s cooperation can be obtained for repeated and prolonged practice such exercises are of considerable value Indeed after a time patients tend to perform the exercises automatically with each expiration The fundamental part of the exercise consists of education to use the abdominal walls as an additional expiratory muscle The hands fix and compress the costal margins with each expiration while the patient makes a blowing effort through partly closed lips After a few moments of such respiration the patient experiences much relief and after a few periods of instruction adopts the practice as a part of his daily routine

If emphysema is limited in extent for example to a single lobe surgical extirpation usually results in marked improvement for a time Further observation is needed to determine whether such benefit is lasting

Acute Respiratory Insufficiency Various intercurrent diseases may produce acute respiratory failure in patients with emphysema Trauma surgical procedures but above all acute upper and lower respiratory infections frequently result in decompensation of the patient s gaseous acidosis Such individuals are cyanotic and stuporous If the patient is to survive heroic measures are required Tracheotomy which allows ready access to the bronchial tree for repeated bronchoscopy or catheter suction is necessary in many cases Oxygen is demanded but its use is fraught with grave danger In the stuporous or near stuporous patient the use of the tank respirator makes it possible to administer oxygen with much less danger Usually it is desirable to administer oxygen by means of a positive pressure machine which produces not only much better ventilation of the areas of air trapping but may also aid in carrying nebulized bronchodilators to more distal bronchioles Some respiratory machines of the positive pressure type have negative pressure phases which produce the effect of cough

If tank respirators are not available oxygen must be administered with extreme caution The patient by reason of obstruction already has a high carbon dioxide pressure for which he is unable to compensate The use of oxygen depresses respiration still further and may result in profound coma If no mechanical device is available manual aid to expiration will have to be used from time to time Oxygen should be administered for 15 min intervals and the patient returned to room air breathing for 10 min intervals If the condition is slightly less severe oxygen at a flow rate of 1 to 2 l per min administered by nasal catheter is safe If respiration is not depressed the rate may be increased 1 l per min each hour until a full flow of 8 to 10 l is reached

Aminophylline—0 5 Gm in 500 ml saline per hour —should be administered and penicillin 600 000 units or other antibiotics may be added when indicated to each bottle of fluid

Cor pulmonale may result from advanced emphysema or from disorders which cause extensive pulmonary fibrosis Its treatment is considered on p 1271

BRONCHIECTASIS

The pathogenesis of bronchiectasis as demonstrated by experiment and supported by clinical observations seems to be the development of a necrotizing bronchitis behind a bronchial obstruction Neither infection nor obstruction alone would seem to be adequate No specific organisms are involved although they are usually anaerobes nor is any specific type of obstruction necessary The dilating force as applied to the diseased bronchial wall is chiefly an external pull due to the negative intrapleural pressure Cough is apparently a result rather than a cause of dilatation

A special type of bronchiectasis that seen in infants with cystic fibrosis of the pancreas is thought to be due to a disorder of mucous glands such that the mucus secreted is extremely tenacious and thick Upper respiratory infections are common among such marasmic infants so that both the obstructive and infective elements are present Since most such infants die in early life the combination of pancreatic fibrosis and bronchiectasis is of interest primarily to pediatricians

Pathologically the diseased lung reveals markedly dilated bronchi between which there is fibrosis and chronic inflammation Distribution conforms to lobes or segments The cartilages are missing in many cases and *oftentimes no residue of the original* bronchial wall can be found In certain areas the walls may be composed of abundantly vascular granulation on a fibrous tissue base while numerous angiomatous capillaries may be seen in other sec

pected The dosage of penicillin recommended is from 10 to 20 million units intravenously daily until the temperature is normal and good clearing is obtained The course of disease should be followed with posteroanterior and lateral films of the chest at 3-day intervals during the first 2 weeks of treatment and thereafter at weekly intervals

The same treatment is applied to subacute or chronic abscesses the most common cause of which is likely to be inadequate early treatment and follow up The duration of treatment is necessarily longer and the results are less satisfactory In almost all such cases perhaps after as long as 4 to 6 weeks a stationary point with from small to large residue is reached The patient by that time is asymptomatic

The problem confronting the physician is whether or not the results—so far as the x ray findings are concerned—are acceptable permanently Frequently it is impossible to decide The problem can usually only be solved by allowing the patient full activity without drugs and following him at regular intervals A return of symptoms even though mild or the occurrence of hemoptysis is indication for resection of the residual lesions

BRONCHIAL OBSTRUCTION ("Atelectasis")

This particular terminology is used not only because the obstruction of the bronchus is the primary and important phenomenon and the change in the lung secondary but also because the lobe or segment beyond the bronchial block is not merely airless but is filled with secretions and bacteria Of much more import than the identification of bacteria beyond the block are the nature and duration of the obstruction itself The cause of the block may be within the bronchus when it may be a foreign body an inflammatory stricture an acute swelling a tumor or merely a mucous plug or extrinsic as in the case of aneurysm mediastinal adenopathy or extrinsic carcinoma Only that atelectasis which arises as a result of compression of the lung from without as by fluid or pneumothorax is relatively benign in character since only in that type is free bronchial drainage available In this instance the remedy of course is the removal of the material producing compression of the lung which upon reexpansion suffers no fibrosis or loss of function except as the pleura may stiffen or adhere

Bronchial obstruction may be recognized by the presence of a lag upon inspiration a decrease in the size of the hemithorax a shift of the mediastinum and trachea to the affected side and elevation of the diaphragm of that side In the acute and earliest stages such as immediately postoperatively there has not been time for solidification of the obstructed segment and dullness is not encountered Breath sounds in such instances however will be diminished and large bubbling sounds may be heard over the hilum This of course is the optimum instant for intervention since most surely no serious damage will have taken place in the lung parenchyma

The x ray examination of the chest in which bronchial obstruction has existed more than a few hours reveals a shift of the trachea and mediastinum a narrowing of the intercostal spaces an elevation of the diaphragm on the affected side and a dense homogeneous shadow which occupies less than the normal volume of the segment or lobe involved Except when obstruction is on the basis of tuberculous bronchitis when the sputum will contain acid fast organisms laboratory studies are of little value

Postoperative bronchial obstruction is so common and so important a complication that it deserves somewhat further description This condition is indeed no more than what has previously been called postoperative pneumonia" "ether pneumonia" or some similar name which obscures the primary fact that the draining bronchi are obstructed by thick and tenacious secretion and that the patient is not able to produce an effective cough Arising most frequently following upper abdominal procedures quite regardless of the type of anesthetic agent used and after chest injury even of slight magnitude bronchial obstruction can be recognized first by an unduly rapid pulse and respiration a slight rise of temperature and by slight suppression of breath sounds usually over a lower lobe area on the side of injury or operation At this stage the roentgenogram reveals no positive findings but is merely indicative of rather poor aeration of both lung fields as a consequence of shallow respiration It is only by about the second or third day that it is possible to obtain the complete picture of atelectasis on physical or x ray examination

The proper treatment instituted at the early phase prevents progression and promptly reverts the vital signs to their proper level Withdrawal of narcotics frequent changes of posture elevation of the foot of the bed directed coughing with the chest or abdomen supported and endotracheal suction by means of catheter are nearly always sufficient to clear the bronchial tree and to reventilate partially obstructed segments It may be noted that in some instances it is necessary to continue these efforts over a period of 2 or 3 days

In more chronic cases of bronchial obstruction bronchoscopy is always indicated to determine the nature of the obstruction and—when the situation permits—to relieve it Finally if bronchoscopy does not suffice to remove the bronchial obstruction the

Much the same effect may be obtained by residence in a warm dry climate supplemented by rigorous postural drainage

ABSCESS OF THE LUNG

Although pulmonary abscess may develop as a result of some specific pneumonias in association with carcinoma of the bronchus and with many varieties of bronchial obstruction and though sometimes multiple abscesses may result from septic embolism or aspiration of stomach contents the term connotes the acute putrid variety that results from anaerobic infection The organism is the anaerobic streptococcus found especially in areas of gingivitis

Pathologically the first step in the process is a severe necrotizing pneumonia usually associated with inflammatory obstruction of the segmental or lobar bronchus involved Within a short time central liquefaction occurs and bronchial drainage begins The cavity that results however is not entirely the result of destruction but in large part derives from a valvelike action in the draining bronchus which steadily inflates the original small hiatus Definite cavitation is usually demonstrable within 5 days and fluid level in the cavity may become apparent very shortly afterward

In the preantibiotic era abscesses were classified as acute if less than 2 weeks in duration subacute if from 2 to 6 weeks in duration and chronic if older than that The practical basis of this classification lay in the fact that response to treatment varied inversely with the duration of disease The pathologic basis for this behavior is that during the first 2 weeks the process is largely exudative with very little fixed change that during the next interval fibrosis begins to fix the cavity wall and that after 6 weeks the changes are fixed and consist of dense fibrosis and bronchiectasis all about the area of original disease as well as of organization of the cavity wall with production of a permanent and unyielding defect These facts should be borne in mind since the results of antibiotic treatment of the abscess are conditioned *at least as much by its* pathologic stage at the initiation of treatment as by varying drug susceptibility of organisms

The antecedent *history* will often elicit as a predisposing cause some type of loss of consciousness so that chronic alcoholism is one of the most closely associated diseases However in a patient with impaired gag reflex or very foul mouth epilepsy head injury general anesthesia or sometimes merely extreme fatigue and very deep sleep may be the precipitating factor

The onset is usually abrupt sometimes with a chill and is manifested by rapidly rising temperature to as high as 105 F Pleuritic pain is usually marked and well localized over the affected segment Cyanosis and dyspnea are present and clubbing develops within a period of as little as two weeks Cough often severe at first is productive of only a scanty mucus but as necrosis progresses the *sputum may become dark green or dark red* with intolerable odor Sometimes when the disease follows its natural course bronchial drainage is marked by a sudden gush of a considerable quantity of malodorous pus and blood If this occurs the temperature frequently drops quickly to a subnormal level and the patient displays sweating and prostration

Physical examination of the chest in most cases reveals a lag due to pleuritic pain marked dullness which can often be established as definitely segmental in location impaired breath and voice sounds and only a few rales The favorite topographic sites for abscess are segments of the lower lobes and the axillary segments of the upper lobes although any portion of the lung may be involved The typical segments are represented by areas lying between the sixth and eighth ribs posteriorly and in the upper lobes high in the axillas

The *chest film* reveals at first a dense patch of pneumonia lying over the eighth posterior rib or just above the fissure line against the lateral chest wall Cavitation is at first slight and the wall appears thick and irregular but as the disease grows older the cavity enlarges the surrounding pneumonia is replaced by atelectasis and fibrosis and the cavity wall appears thinner Fluid level is frequent but is not necessary for roentgenologic diagnosis Lateral films will assist in the exact localization

During the acute stage of the disease there is marked elevation of the total white count with a neutrophilic leukocytosis and a left shift Sputum cultures are needed to exclude tuberculosis and fungi and to obtain drug sensitivity tests

The acute pneumonic phase of abscess has to be differentiated from ordinary pneumococcal pneumonia Poor oral hygiene a history of stupor or unconsciousness diminished breath and voice *sounds in the area of disease characteristic lo*calization within the chest and failure to respond within 24 hr to doses of penicillin adequate for pneumococcal disease are important points

Subacute and chronic abscesses must be differentiated from tuberculosis mycotic diseases and carcinoma Sputum smears and cultures and bronchoscopy are necessary measures particularly since some abscesses may have a gradual rather than dramatic onset

Treatment The treatment of all abscesses regardless of stage is at first medical In patients whose disease is treated within 2 weeks of the onset essentially complete resolution may be ex

ACUTE DIFFUSE INTERSTITIAL FIBROSIS

Described by Hamman and Rich this progressive interstitial infiltration of the lung is manifest clinically as a progressive pulmonary infection distinguished by intense dyspnea and gradually increasing hypoxia Cough is usually nonproductive Temperature ranges from 101 F upward the pulse is unduly accelerated and *cyanosis is unrelieved by oxygen* Over the chest a few medium moist rales may be heard in various areas and sometimes it is *possible to distinguish zones of consolidation* The white blood count is only moderately elevated and the film of the chest reveals nondescript pneumonic *infiltrations*

A more chronic type of diffuse interstitial fibrosis which presents extensive miliarylike infiltrations has been described under this same syndrome While in the disease as originally described death took place in from 6 to 16 weeks individuals have survived the miliary type for 2 or 3 years although hopelessly handicapped by dyspnea and hypoxia

Attempts to control this disease with ACTH and corticoids may have resulted in some amelioration of symptoms and prolongation of life Withdrawal *or reduction in dosage of these drugs may* result in rapid progression Patients who live longer than a few weeks usually present pictures of cor pulmonale and have to be treated as described (see p 1272)

LOEFFLER S SYNDROME

Transient pulmonary infiltration and eosinophilia together with few or no clinical symptoms characterize a *syndrome described in* 1929 by Loeffler Roentgenograms show unilateral or bilateral pulmonary infiltrations often fan shaped and homogeneous but these disappear in 1 or 2 weeks In Loeffler s cases the cause was unknown but similar changes have been observed in cases of cutaneous helminthiasis (*Ancylostoma braziliense*) in clonorchiasis in association with infestation with the parasites *Ascaris lumbricoides Necator americanus Strongyloides stercoralis Fasciola hepatica* and *Trichinella spiralis* in infection due to *Coccidioides immitis* in contact with the privet flower and in sulfonamide or barbiturate sensitization

Probably to be distinguished from Loeffler s syndrome is *tropical eosinophilia* a disorder which is accompanied by cough and expectoration and all the manifestations of bronchial asthma even status asthmaticus This condition has been observed particularly in natives of India and Ceylon and even among Indians living outside their country The leukocyte count is often greater than 20 000 per cubic *millimeter and the proportion of eosinophils* above 60 per cent This disorder responds promptly to arsenical therapy but relapses are not unusual

There have been few opportunities to study the pathology of these disorders In four patients with Loeffler s syndrome whose deaths were accidental the pulmonary lesions were found to consist of bronchitis bronchiolitis or pneumonia with eosinophils in the exudate and in the alveolar septums A similar disorder has been produced experimentally by the intratracheal instillation of horse serum in rabbits previously injected with the serum *Eosinophils were found in the tracheal and* bronchial mucosa congestion edema atelectasis emphysema and eosinophilic pneumonia were *found in the lungs This evidence suggests that* Loeffler s syndrome may arise from an immune reaction which takes place principally in the lungs In some of the cases of tropical eosinophilia the striking findings have been vascular and have ranged from intimal thickening of the small arteries to necrotizing arteritis with perivascular eosinophilia

only measure to be considered is resection of the blocked segment

BRONCHOLITHIASIS

Broncholithiasis is described as a condition in which pieces of calcium of varying size roughness and irregularity are coughed out of the bronchial tree In most instances the origin of the calcium seems to be from tuberculous lymph nodes in the hilar area For unknown reasons the calcium begins to work its way out of its matrix of dense hyaline fibrous tissue and to erode into adjacent bronchi

The symptoms usually consist of repeated and rather copious hemoptyses In many instances the patient himself will report that he has coughed up fragments of gravel" Rarely is there consolidation or obstruction of the lobe from the bronchus which is being eroded Fever may occur briefly following hemoptysis and is relatively unimportant other systemic symptoms are usually absent

The diagnosis is made by the discovery either in sputum or at bronchoscopy of characteristic irregular calcium fragments The presence of dense calcification about the hilum of the lung might raise the suspicion of this condition if no other cause of hemoptysis can be demonstrated Sputum should be repeatedly searched for tubercle organisms although this effort is usually unproductive and patients with broncholithiasis on a tuberculous basis rarely if ever develop active pulmonary disease even though they may have been followed for many years

The treatment consists of reassurance once an absolute diagnosis is reached If hemoptyses are small and occur at long intervals no further measure is necessary However if hemoptyses have been large and tend to be persistent or quite frequent the only possible attack consists of the removal of the damaged bronchus and its corresponding parenchymal division Since the dissection of the hilum particularly about the pulmonary vessels is often very difficult in patients with broncholithiasis the surgeon may sometimes find himself forced either to abandon the procedure or to perform a pneumonectomy Such an outcome should be kept in mind when the problem is discussed with the patient

CHRONIC ORGANIZING PNEUMONIA
(Chronic Fibroid or Interstitial Pneumonia)

This condition in which a primary exudative reaction fails to resorb and is replaced by lymphocytic reaction and eventual fibrous change is not a primary condition but is a part of the pathologic picture in areas adjacent to chronic suppuration of the lung It is regularly present behind bronchial obstructions and in areas of incompletely resolved pneumonia as well as surrounding carcinoma abscess or bronchiectasis One of its most potent causes is bronchial obstruction The best treatment is prevention when that is possible To this end repeated bronchoscopy is often of considerable value Other measures which afford considerable benefit consist of expectorants steam inhalation and nebulized wetting agents such as Alevaire and ferments such as Tryptar Once the acute and reversible infiltration has given place to organization none of these measures has any value The patient s complaints must then be evaluated against the risks of surgical resection In many individuals resection may prove unnecessary if the patient is willing to discipline himself to the mode of life previously described under Chronic Bronchitis

CYSTIC DISEASE OF THE LUNG

Although some authorities regard all cysts as congenital in origin the consensus is that in most instances they are acquired In the newborn one occasionally encounters very large single cysts which rapidly replace an entire lung and closely simulate spontaneous pneumothorax In adults one may occasionally see single cysts which from time to time vary in size and which may eventually become infected Dyspnea due to partial compression of adjacent tissue and to the effect of the high carbon dioxide content of the poorly ventilated cyst is quite common and may be completely relieved following resection of the structure Hemoptysis may be a presenting complaint In patients without symptoms observation is sufficient but sooner or later nearly all cysts become infected or prove annoying enough to require resection

Multiple cysts of the lung are usually distributed bilaterally and give rise to a history closely resembling that of bronchiectasis On physical examination the chest is usually overdistended and presents findings characteristic of emphysema except that many moist rales may be encountered in some patients Numerous wheezes also may sometimes be heard

The x ray reveals circular shadows varying in diameter from 1 to 10 cm and scattered about both lungs In some of these there may be fluid levels but in spite of infection the walls remain quite thin Studies other than bronchography are unrevealing Iodized oil in such cases reveals irregular beaded dilatations of the smaller bronchi and bronchioles Hence the alternate name cystic bronchiolectasis Since the situation is irreparable if bilateral the treatment is palliative and does not differ from that of nonsurgical bronchiectasis

ACUTE DIFFUSE INTERSTITIAL FIBROSIS

Described by Hamman and Rich this progressive interstitial infiltration of the lung is manifest clinically as a progressive pulmonary infection distinguished by intense dyspnea and gradually increasing hypoxia Cough is usually nonproductive Temperature ranges from 101 F upward the pulse is unduly accelerated and cyanosis is unrelieved by oxygen Over the chest a few medium moist rales may be heard in various areas and sometimes it is possible to distinguish zones of consolidation The white blood count is only moderately elevated and the film of the chest reveals nondescript pneumonic infiltrations

A more chronic type of diffuse interstitial fibrosis which presents extensive miliarylike infiltrations has been described under this same syndrome While in the disease as originally described death took place in from 6 to 16 weeks individuals have survived the miliary type for 2 or 3 years although hopelessly handicapped by dyspnea and hypoxia

Attempts to control this disease with ACTH and corticoids may have resulted in some amelioration of symptoms and prolongation of life Withdrawal or reduction in dosage of these drugs may result in rapid progression Patients who live longer than a few weeks usually present pictures of cor pulmonale and have to be treated as described (see p 1272)

LOEFFLER S SYNDROME

Transient pulmonary infiltration and eosinophilia together with few or no clinical symptoms characterize a syndrome described in 1929 by Loeffler Roentgenograms show unilateral or bilateral pulmonary infiltrations often fan shaped and homogeneous but these disappear in 1 or 2 weeks In Loeffler s cases the cause was unknown but similar changes have been observed in cases of cutaneous helminthiasis (*Ancylostoma brasiliense*) in clonorchiasis in association with infestation with the parasites *Ascaris lumbricoides Necator americanus Strongyloides stercoralis Fasciola hepatica* and *Trichinella spiralis* in infection due to *Coccidioides immitis* in contact with the privet flower and in sulfonamide or barbiturate sensitization

Probably to be distinguished from Loeffler s syndrome is *tropical eosinophilia* a disorder which is accompanied by cough and expectoration and all the manifestations of bronchial asthma even status asthmaticus This condition has been observed particularly in natives of India and Ceylon and even among Indians living outside their country The leukocyte count is often greater than 20 000 per cubic millimeter and the proportion of eosinophils above 60 per cent This disorder responds promptly to arsenical therapy but relapses are not unusual

There have been few opportunities to study the pathology of these disorders In four patients with Loeffler s syndrome whose deaths were accidental the pulmonary lesions were found to consist of bronchitis bronchiolitis or pneumonia with eosinophils in the exudate and in the alveolar septums A similar disorder has been produced experimentally by the intratracheal instillation of horse serum in rabbits previously injected with the serum Eosinophils were found in the tracheal and bronchial mucosa congestion edema atelectasis emphysema and eosinophilic pneumonia were found in the lungs This evidence suggests that Loeffler s syndrome may arise from an immune reaction which takes place principally in the lungs In some of the cases of tropical eosinophilia the striking findings have been vascular and have ranged from intimal thickening of the small arteries to necrotizing arteritis with perivascular eosinophilia

238 NEOPLASTIC DISEASES

Champ Lyons

CARCINOMA OF THE BRONCHUS

The great majority of the neoplasms of the lung arise within the wall or epithelial lining of the bronchus either centrally or peripherally About half of all bronchogenic carcinomas are squamous cell types About one third are highly anaplastic and are designated as undifferentiated carcinoma These two types occur predominantly in males There is considerable sentiment to indict the smoking of cigarettes in the genesis of lung cancer but there are still two sides to the question More clearly carcinogenic are the industrial exposures in the mining of radioactive ores the refining of nickel the manufacture of chromates and coal gas and the processing of arsenic and asbestos The siliceous dusts as encountered in mining do not seem to increase the vulnerability of the lung to cancer

About one fifth of bronchogenic cancers are adenocarcinoma These occur with almost equal frequency in females and it has been suggested that they arise from embryonic bronchial buds They are usually highly malignant

Early lymphatic and vascular invasion are so constantly a feature of bronchogenic carcinoma that initial symptoms in many cases are attributable *to metastases These involve the mediastinal and* supraclavicular lymph nodes brain bone adrenal cortex liver and subcutaneous tissues Tumors arising in the apex of the lung may invade directly the brachial plexus and subclavian vessels producing neuritic pain Horner s syndrome and vasomotor crises in the hand and arm the *Pancoast syndrome of superior sulcus tumor* Secondary involvement of the superior mediastinum may compress the superior vena cava with resulting edema and venous suffusion of the face neck and arms the *superior vena caval syndrome* Less frequently direct invasion of the esophagus behind the heart may be responsible for obscure dysphagia

Another pattern of symptoms is to be attributed to the encroachment of the tumor upon the lumen of the bronchus or bronchiole With partial occlusion of the lumen there is persistent cough asthmatic breathing and x ray evidence of localized emphysema *As the obstruction becomes complete* there is atelectasis recurrent pneumonitis distal bronchiectasis and occasionally lung abscess Hemoptysis is fairly common in both the early and the late stages Painfully swollen joints *(pulmonary osteoarthropathy) and clubbing may* occur

Apart from the demonstration of localized emphysema and segmental atelectasis the most suggestive x ray finding is that of a hilar density extending peripherally (see Fig 167) Bronchoscopy permits visualization and biopsy of the primary tumor in 40 to 60 per cent of the cases Cytologic study of the sputum in expert hands may permit diagnosis in 85 per cent and is especially useful for peripheral tumors Early recourse to exploratory thoracotomy with biopsy of the primary tumor or regional nodes *is the procedure of choice* in any controversial diagnosis Contrast bronchography is rarely indicated

The treatment of choice for bronchogenic carcinoma is radical pneumonectomy It is of great clinical concern that about one half of the symptomatic patients presenting at an average lapse of 5 months from onset are rejected for operation on the basis of local extension or distant metastases About one third of the symptomatic cases prove to be resectable and the 5 year survival rate is about 6 per cent In older patients with reduced respiratory reserve less radical resections such as lobectomy or partial pneumonectomy with plastic reconstruction of the bronchus have proved practical without apparent reduction in the salvage rate X ray treatment and nitrogen mustard therapy occasionally retard the rate of growth and spread

Identification of the presence of a tumor before the onset of symptoms remains the chief hope for greater salvage Mass radiography for tuberculosis

has provided numerous instances of the silent and solitary nodule" Many of these have proved to be totally resectable cancers The problem of early recognition of cancer of the lung is now so pressing that all males over forty should have x ray examination of the chest at intervals of 6 months It is to be expected that refinement of cytologic techniques may contribute to early diagnosis

Carcinoma of the bronchus should also be suspected whenever any individual in the susceptible age group shows delayed resolution of any intrapulmonary inflammation The unresolved pneumonia or a lung abscess or pneumonia recurrent in the same lobe in males over forty should invite immediate study for tumor

BRONCHIOLAR CARCINOMA

This disease has been known as *pulmonary adenomatosis* but the ultimately fatal outcome and the increasing recognition of regional and distant metastases render suspect the identity of completely benign pulmonary adenomatosis It is not certain whether the tumor cells are derived from the basal cells of the terminal bronchioles or from the lining membrane of the alveoli Usage dictates preference for *alveolar cell carcinoma* or *bronchiolar carcinoma* There occurs in sheep a contagious disease of presumptive viral etiology known as *jaag iekte* in South Africa and as *Montana chronic progressive pneumonia* in the United States This disease is not transmissible to man but is characterized by hyperplasia of cuboidal epithelial cells within the alveoli in striking similarity to the neoplastic disease of man

The tumor appears to arise from multicentric foci and ultimately involves both lungs Both sexes are susceptible and the usual age of onset is in the fourth and fifth decades Symptoms begin insidiously often following an acute respiratory infection Cytologic examination of the sputum even in early cases frequently reveals tumor cells Dyspnea because of faulty gas exchange is out of proportion to x ray findings Cough productive of the typically viscid pinkish sputum is a manifestation of the tumor Terminally there is frank hemoptysis with clubbing intense cyanosis recurrent pneumonitis and evidence of metastasis Nodular and confluent patterns of the disease are recognized

The treatment of choice is surgical excision of the initially involved lobe or lobes when practical There is some hope of palliation by x ray therapy but nitrogen mustard appears useless

ADENOMA OF THE BRONCHUS

The bronchial adenoma is a locally invasive and occasionally metastasizing tumor derived from the

Fig 167 Carcinoma of the bronchus

mucous glands of the bronchus and requiring separate classification from the more rapidly growing bronchogenic carcinomas It constitutes about 3 per cent of all lung tumors and differs from bronchogenic carcinoma in that it is usually apparent before the fifth decade lacks sexual predilection and develops metastases persisting for long periods without apparent change

Histologically the adenomas show a peculiar epithelial proliferation and an equally peculiar stroma Inclusions of bone are thought to represent metaplasia from chronic infection The mixed tumor (cylindroma) type (10 per cent) is somewhat more invasive than the carcinoid adenoma (90 per cent) There is still controversy about these tumors as regards etiology the occurrence of mixed types the absence of argentaffin granules in the types designated is carcinoid and their relationship to other polypoid tumors of the bronchial wall

The adenoma syndrome is the clinical consequence of the slow growth of a vascular tumor producing major bronchial occlusion in a young person i e hemoptysis asthmatic wheezes obstructive emphysema recurrent pneumonitis and the complications therefrom bleeding atelectasis bronchiectasis pleuritis lung abscess and empyema The lower lobes are more often affected and there is a slightly greater incidence on the right side Contrast radiography (bronchography or tomography) often demonstrates the tumor but routine x rays are noncontributory in about one fifth of the cases About 90 per cent of the tumors may be recognized bronchoscopically by their polypoid appearance mobility vascularity and absence of

CARCINOMA OF THE BRONCHUS

The great majority of the neoplasms of the lung arise within the wall or epithelial lining of the bronchus either centrally or peripherally About half of all bronchogenic carcinomas are squamous cell types About one third are highly anaplastic and are designated as undifferentiated carcinoma These two types occur predominantly in males There is considerable sentiment to indict the smoking of cigarettes in the genesis of lung cancer but there are still two sides to the question More clearly carcinogenic are the industrial exposures in the mining of radioactive ores the refining of nickel the manufacture of chromates and coal gas and the processing of arsenic and asbestos The siliceous dusts as encountered in mining do not seem to increase the vulnerability of the lung to cancer

About one fifth of bronchogenic cancers are adenocarcinoma These occur with almost equal frequency in females and it has been suggested that they arise from embryonic *bronchial buds* They are usually highly malignant

Early lymphatic and vascular invasion are so constantly a feature of bronchogenic carcinoma that initial symptoms in many cases are attributable to metastases These involve the mediastinal and supraclavicular lymph nodes brain bone adrenal cortex liver and subcutaneous tissues Tumors arising in the apex of the lung may invade directly the brachial plexus and subclavian vessels producing neuritic pain Horner s syndrome and vasomotor crises in the hand and arm the *Pancoast syndrome of superior sulcus tumor* Secondary involvement of the superior mediastinum may compress the superior vena cava with resulting edema and venous suffusion of the face neck and arms the *superior vena caval syndrome* Less frequently direct invasion of the esophagus behind the heart may be responsible for obscure dysphagia

Another pattern of symptoms is to be attributed to the encroachment of the tumor upon the lumen of the bronchus or bronchiole With partial occlusion of the lumen there is persistent cough asthmatic breathing and x ray evidence of localized emphysema As the obstruction becomes complete there is atelectasis recurrent pneumonitis distal bronchiectasis and occasionally lung abscess Hemoptysis is fairly common in both the early and the late stages Painfully swollen joints (pulmonary osteoarthropathy) and clubbing may occur

Apart from the demonstration of localized emphysema and segmental atelectasis the most suggestive x ray finding is that of a hilar density extending peripherally (see Fig 167) Bronchoscopy permits visualization and biopsy of the primary tumor in 40 to 60 per cent of the cases Cytologic study of the sputum in expert hands may permit diagnosis in 85 per cent and is especially useful for peripheral tumors Early recourse to exploratory thoracotomy with biopsy of the primary tumor or regional nodes is the procedure of choice in any controversial diagnosis Contrast bronchography is rarely indicated

The treatment of choice for bronchogenic carcinoma is radical pneumonectomy It is of great clinical concern that about one half of the symptomatic patients presenting at an average lapse of 5 months from onset are rejected for operation on the basis of local extension or distant metastases About one third of the symptomatic cases prove to be resectable and the 5 year survival rate is about 6 per cent In older patients with reduced respiratory reserve less radical resections such as lobectomy or partial pneumonectomy with plastic reconstruction of the bronchus have proved practical without apparent reduction in the salvage rate X ray treatment and nitrogen mustard therapy occasionally retard the rate of growth and spread

Identification of the presence of a tumor *before the onset of symptoms* remains the chief hope for greater salvage Mass radiography for tuberculosis

appear after removal of the tumor The diffuse mesotheliomas require difficult differentiation from metastatic anaplastic carcinoma with pleural effusion and are characterized by a comparably intractable course Treatment is limited to repeated thoracenteses radiation therapy and instillation of radioactive gold as palliative procedures

The Solitary Pulmonary Nodule Occasionally a roentgenogram of the chest may reveal a nodule less than 6 cm in diameter which is fairly sharply delineated from adjacent pulmonary tissue Such lesions have been designated *solitary pulmonary nodules* in preference to the term *coin lesions* About one third of these are peripheral bronchogenic carcinomas demonstrable as such only after excision and surviving in 75 per cent of the patients when treated usually by simple lobectomy In the absence of other diagnostic aids thoracotomy is indicated by the x ray findings in most cases Ten per cent of such lesions are metastatic neoplasms and about half are granulomas with histoplasma tuberculosis and coccidioidomycosis responsible in that order Hamartomas lipid granulomas lipid granulomas from oily nose drops and pulmonary sequestrations also produce this picture A non operative program of continued observation may be elected when a review of earlier films demonstrates no change over a period of 5 years but it should be realized that such nodules have been followed for 8 years only to declare themselves as cancers Considerable interest in radiologically demonstrable calcium deposits has demonstrated that flecks" of calcium may occur in bronchogenic cancers A central core or concentric lamellations of calcium are indicative of granuloma

239 DISORDERS DUE TO ASPIRATED FOREIGN BODIES

John S Chapman

The aspiration of large foreign bodies which is encountered most commonly in children is marked by the sudden onset of strangling choking coughing and cyanosis If the object is small enough to pass down to a lobar or branch bronchus the acute picture subsides for a few days and then the syndrome presented is that of bronchial obstruction with suppuration beyond particularly when the offending substance is vegetable In other cases if the body is nonabsorbable after coming to rest in one branch bronchus with a subsidence of symptoms it may after a few days become dislodged and again repeat the original episode as it is shuttled about in the trachea and major bronchi There is only one treatment—bronchoscopy with removal

Lipid Pneumonia This condition results from the aspiration of oily material and occurs most commonly in patients who have ingested large quantities of mineral oil over a prolonged period or in infants or adults who have been subjected to the use of oily nose drops In a limited area and to a minor extent a lipid pneumonia probably takes place following every injection of iodized oil The histologic picture is that of foreign body giant cell reaction with lymphocytes and mononuclear leukocytes In chest films one usually finds a bilateral lower lobe distribution which is patchy and irregular but occasionally the infiltration may be found involving other areas and even single segments The earliest phase is said to be indicated only by increased basilar markings The sputum examined fresh under the cover glass reveals numerous free fat droplets as well as phagocytes filled with oil droplets which take up Sudan III

No treatment is indicated for lipid pneumonia and the condition is of importance chiefly from the fact that a problem of differential diagnosis arises as a result of routine film of the chest Obviously a cessation of the use of oil is necessary to prevent the development of additional areas of infiltration

Aspirational (Enzymatic) Pneumonia This type of pneumonia is the result of the aspiration of gastric contents Usually a period of unconsciousness associated with vomiting as in acute alcoholism suicidal efforts head injury or rough anesthesia is a major predisposing factor Occasionally similar types of illness follow tracheoesophageal fistulas as a result of carcinoma in adults or as a congenital anomaly in infants The so called esophageal spill over syndrome associated with esoph

FIG 168 Hematogenous metastasis from sarcoma of the ileum clinically marked by intense dyspnea and cyanosis (*Courtesy Dr C L Martin*)

ulcerations The vascularity dictates caution in the indicated biopsy The lack of ulceration explains the absence of tumor cells in sputum and bronchial washings

Older methods of piecemeal excision by repeated bronchoscopic nibblings have largely been replaced by direct surgical removal of the primary tumor the involved hilar lymph nodes and the secondarily diseased lung Exceptions to pneumonectomy consist of lobectomy for the more peripheral tumor without involvement of hilar nodes and bronchotomy for the small tumor with a tiny stalk Long term survival is the rule especially for the carcinoid adenomas Mediastinal recurrence and hepatic metastases are an especial hazard of the mixed tumor adenomas (cylindromas) There is some evidence to suggest that true bronchogenic carcinoma may occasionally develop within an adenoma

METASTATIC TUMORS OF THE LUNG

Metastasis to the lung results from infarction with tumor emboli carried by the peripheral veins The x ray appearance is frequently characteristic and may appear as a solitary cannonball nodule multiple nodules (see Fig 168) or miliary dissemination known as *lymphangitic carcinomatosis* (see Fig 169) It is hazardous to make an x ray diagnosis of lymphangitic carcinomatosis of the lung in the absence of clinical evidence of alveolar capillary block namely severe dyspnea and obvious cyanosis Sarcomas hypernephromas melanomas and tumors of the testicle breast thyroid and pancreas seem to find the lung an especially favorable site for the growth of metastases

Dyspnea and pleuritic pain are the cardinal symptoms of lung metastases Erosion into the bronchial tree may be associated with cough hemoptysis and occasionally with tumor cells in the sputum Treatment is largely palliative with opiates and repeated thoracenteses to relieve the pain and dyspnea Irradiation may prove helpful for sensitive tumors but more reliance is placed upon hormonal or isotope approaches for specific tumors

In the course of exploratory thoracotomy for asymptomatic solitary nodules it occasionally happens that a metastasis from a previously unidentified primary tumor is found The ground rules for deliberate surgical excision of solitary lung metastases include prior control of the primary focus lapse of a reasonable length of time between initial treatment and appearance of the lung metastasis and absence of other areas of tumor recurrence

Primary Tumors of the Pleura Localized pleural tumors are usually proved to be mesenchymomas of subpleural mesodermal elements or granulomatous inclusion cysts complicating interlobular inflammation Primary pleural neoplasms are restricted to the mesothelioma This may occur as a localized tumor frequently arising from the visceral pleura or embedded in the lung and distinctively associated with clubbing and arthralgia which dis

FIG 169 So called "lymphangitic carcinomatosis" metastatic from a carcinoma of the cervix (*Courtesy Dr C L Martin*)

respiratory tract whereas others affect chiefly the deeper structures of the lung, is partly attributable to their varying solubility in water Ammonia formaldehyde hydrofluoric and hydrochloric acid are so soluble as to attack the first moist surface with which contact is made The concentration of these chemicals in the air going to the deep parts of the lung is thus reduced to some extent on the way through the upper passages and pulmonary injury is lessened In contrast nitrogen dioxide (nitrous fume) phosgene and cadmium oxide fumes are relatively less soluble and hence less irritating to the upper respiratory tract They can be respired without great discomfort and reach the deeper parts of the lung in atmospheric concentration that may be exceedingly injurious The reaction to these chemicals is delayed but often far more serious than that to those causing more immediate discomfort In fact the lack of distress immediately upon inhalation makes these gases especially dangerous Midway between these two groups in solubility and action are sulfur dioxide the halogens and hydrogen sulfide

Treatment of the acute reaction depends little or not at all upon the recognition of the specific noxious agent responsible for the event Therapy is directed first at overcoming the alterations of physiology Shock must oftentimes be combated Oxygen in concentrations of 50 per cent or more is imperative There is little scientific support for the use of positive pressure by mask although a priori reasoning has prompted its use Practical experience has shown that physical struggle and unrest may cause sudden death If positive pressure during inspiration makes breathing less of an effort and is tolerated without restlessness it is not contraindicated except in shock In the hypotensive state due to poor venous return positive pressure breathing is contraindicated The use of agents which lower the surface tension of serum might be useful when administered via the airway as recommended in pulmonary edema of circulatory origin but the author has no information on this point Sedation is very important Bromides appear to be preferable to barbiturates Morphine is contraindicated The prophylactic use of antibacterials is recommended throughout the period of pulmonary inflammation

Other relatively acute reactions of the lung to inhaled material are noteworthy because of the long delay between initial contact and the reaction Although exposure to high concentrations of a fume thought to be anhydrous beryllium sulfate may cause a violent chemical pneumonitis in a few to 72 hr a much more insidious chemical pneumonia (not to be confused with the chronic granuloma discussed later) is also known to occur in the beryllium extraction industry and in other exposures where beryllium fluoride and beryllium oxide are inhaled In this reaction which develops weeks or even months after exposure begins the symptoms of dyspnea on exertion paroxysmal cough substernal pain weakness and weight loss may precede the development of any abnormal shadows seen in the roentgenogram of the chest by 1 to 3 weeks When abnormal shadows develop they are characterized by a granular haziness of a diffuse patchy distribution which in some instances may be fluffy in appearance The pathology is that of a true chemical pneumonia Treatment is the same as for the acute reactions described before This disease is apt to persist for several weeks and treatment must be continued throughout The use of ACTH or cortisone has not received adequate trial but should be explored Recovery is the rule but fatalities do occur

A rather rare disease brought about by the inhalation of bagasse dust has been described in workers preparing bagasse from sugar cane or using it in manufacture The true etiologic factor is unknown but its association with bagasse seems established and for the present the disease might be properly included under the heading of this chapter Weeks to months after the beginning of exposure to bagasse dust the disease makes its presence known by severe paroxysmal cough and dyspnea Fever may persist for weeks or months The lung shows evidence of resistance to expansion Cyanosis may be present The white blood count is elevated the polymorphonuclear cells forming 70 to 90 per cent of the total The clinical picture is that of a diffuse pneumonia which persists for weeks The scant tissue available for study shows an interstitial fibroelastic reaction The pulmonary roentgenogram shows an abnormal diffuse pattern of fine stippling Recovery is slow but usually occurs and few if any sequelae remain Treatment is symptomatic The use of ACTH or cortisone has not been reported

Chronic Reactions As mentioned earlier the majority of the various kinds of material inhaled and deposited in the lung cause no tissue reaction Particles larger than 10 μ in size are not found in the deeper parts of the lung but those of smaller size do reach the alveoli where they are engulfed by phagocytes Soluble particles such as marble or gypsum disappear entirely while those less soluble or insoluble particles are carried by the phagocytes to the lymphoid collection of the lung and mediastinum and there deposited Many of the insoluble varieties of dust are inert so far as tissue reaction is concerned and do not cause significant fibrosis The particles of such substances as iron soot etc simply remain in the lymphoid tissue along the course of the lymphatic and blood vessels that accompany the bronchial tree If present in large enough quantities these inert substances may

ageal stricture or obstruction without fistula produces a somewhat similar type of pulmonary disease

Both lower lobes usually reveal a very intense bronchopneumonic infiltration Acute necrosis leads to the formation of abscesses toward the termination of smaller bronchi These abscesses are notable for the absence of fibrous tissue reaction and for the fact that their walls consist principally of a slimy membrane beyond which is a zone of intense necrosis The peculiarities of this reaction are thought to be the result of the action of gastric ferments on pulmonary tissue The tissue reaction resembles that of abscesses due to the aspiration of vegetable foreign material

The clinical picture is that of an acutely ill patient with marked dyspnea and cyanosis The lower lobe areas present moderate reduction in breath sounds and fairly numerous moist rhonchi and rales Polymorphonuclear leukocytosis is marked The sputum may contain identifiable gastric contents and it may be possible to demonstrate peptic activity in expectorated material Roentgenograms reveal patchy infiltrations bilaterally but it is often impossible to distinguish individual abscesses

The treatment for all these conditions is repeated bronchoscopic aspiration the use of large doses of penicillin and in the fistula cases efforts to correct the condition In the case of the adult whose carcinoma of the esophagus (see Chap 243) has invaded the bronchus or trachea there is of course the possibility of gastrostomy as a partially palliative measure The outlook in such instances is so bad and the usual duration of life so short after perforation that there is little chance for intervention and even less that the intervention will be successful

240 PULMONARY DISORDERS DUE TO INHALATION OF NOXIOUS AGENTS

George W Wright

General Considerations For centuries it has been recognized that certain particulate substances cause no untoward effects even when inhaled for many years whereas others may rapidly or gradually cause pulmonary changes that vary considerably in degree of severity and seriousness The number of known pathogenic substances continues to increase with the recognition of previously obscured relationships and with the development of new substances or new situations to which men may be exposed

The body response to these noxious agents is of two broad categories acute pneumonitis and chronic granuloma with fibrosis The acute response may be immediate or delayed hours or even days after the contact in the chronic form there is with one exception a history of prolonged exposure and a delay in development of the body reaction Because of the trend toward a delayed reaction the inciting cause may be difficult to discover except by the most painstaking anamnesis In no other category of disease is the past history more important and at the same time apt to be so poorly explored Most physicians have little contact with and knowledge of specific working conditions in industry and hence they are likely to be ill prepared to take an occupational history No occupational history is adequate until the activities and surroundings of the patient during every year of his life are accounted for and the potential for hazard of each specific occupation is known

Acute Reactions The acute pulmonary injuries usually arise from the inhalation of irritant vesicatory or necrotizing gases or fumes Certain gases have an immediate powerful irritating action which is characterized by lachrymation burning and pain of the nose pharynx and trachea and by severe cough Strong concentrations may cause such severe irritation as to bring about prompt cessation of respiration allegedly by laryngeal spasm If the subject survives the immediate effects of the gas pulmonary edema may ensue with subsequent recovery or death in spite of all efforts to provide relief Other gases for example the nitrous fumes of detonated blasting powder or burning celluloid may not cause such severe immediate reactions as to be unduly alarming but after a delay of several hours the patient may rather rapidly develop severe respiratory distress cyanosis and shock with all the signs of pulmonary edema and exudate Because serious delayed reaction is possible it is wise to keep all persons who have been exposed to unusual concentrations of the irritating gases under close scrutiny for at least 24 hours Some degree of inflammation and necrosis of tissue always occurs following severe pulmonary reactions and during this period the lungs are unusually susceptible to bacterial infection Recovery may occur by resolution of the edema and inflammatory products or by fibrous replacement Commonly there are no recognizable residua or sequelae

That certain gases act primarily on the upper

respiratory tract whereas others affect chiefly the deeper structures of the lung is partly attributable to their varying solubility in water Ammonia formaldehyde hydrofluoric and hydrochloric acid are so soluble as to attack the first moist surface with which contact is made The concentration of these chemicals in the air going to the deep parts of the lung is thus reduced to some extent on the way through the upper passages, and pulmonary injury is lessened In contrast nitrogen dioxide (nitrous fume) phosgene and cadmium oxide fumes are relatively less soluble and hence less irritating to the upper respiratory tract. They can be respired without great discomfort and reach the deeper parts of the lung in atmospheric concentration that may be exceedingly injurious The reaction to these chemicals is delayed but often far more serious than that to those causing more immediate discomfort In fact the lack of distress immediately upon inhalation makes these gases especially dangerous Midway between these two groups in solubility and action are sulfur dioxide the halogens and hydrogen sulfide

Treatment of the acute reaction depends little or not at all upon the recognition of the specific noxious agent responsible for the event Therapy is directed first at overcoming the alterations of physiology Shock must oftentimes be combated Oxygen in concentrations of 50 per cent or more is imperative There is little scientific support for the use of positive pressure by mask although a priori reasoning has prompted its use Practical experience has shown that physical struggle and unrest may cause sudden death If positive pressure during inspiration makes breathing less of an effort and is tolerated without restlessness it is not contraindicated except in shock In the hypotensive state due to poor venous return positive pressure breathing is contraindicated The use of agents which lower the surface tension of serum might be useful when administered via the airway as recommended in pulmonary edema of circulatory origin but the author has no information on this point Sedation is very important Bromides appear to be preferable to barbiturates Morphine is contraindicated The prophylactic use of antibacterials is recommended throughout the period of pulmonary inflammation

Other relatively acute reactions of the lung to inhaled material are noteworthy because of the long delay between initial contact and the reaction Although exposure to high concentrations of a fume thought to be anhydrous beryllium sulfate may cause a violent chemical pneumonitis in a few to 2 hr a much more insidious chemical pneumonia (not to be confused with the chronic granuloma discussed later) is also known to occur in the beryllium extraction industry and in other exposures w[illegible]de and beryllium oxide are inhaled In this reaction which develops weeks or even months after exposure begins the symptoms of dyspnea on exertion paroxysmal cough substernal pain weakness and weight loss may precede the development of any abnormal shadows seen in the roentgenogram of the chest by 1 to 3 weeks When abnormal shadows develop they are characterized by a granular haziness of a diffuse patchy distribution which in some instances may be fluffy in appearance The pathology is that of a true chemical pneumonia Treatment is the same as for the acute reactions described before This disease is apt to persist for several weeks and treatment must be continued throughout The use of ACTH or cortisone has not received adequate trial but should be explored Recovery is the rule but fatalities do occur

A rather rare disease brought about by the inhalation of bagasse dust has been described in workers preparing bagasse from sugar cane or using it in manufacture The true etiologic factor is unknown but its association with bagasse seems established and for the present the disease might be properly included under the heading of this chapter Weeks to months after the beginning of exposure to bagasse dust the disease makes its presence known by severe paroxysmal cough and dyspnea Fever may persist for weeks or months The lung shows evidence of resistance to expansion Cyanosis may be present The white blood count is elevated the polymorphonuclear cells forming 70 to 90 per cent of the total The clinical picture is that of a diffuse pneumonia which persists for weeks The scant tissue available for study shows an interstitial fibroelastic reaction The pulmonary roentgenogram shows an abnormal diffuse pattern of fine stippling Recovery is slow but usually occurs and few if any sequelae remain Treatment is symptomatic The use of ACTH or cortisone has not been reported

Chronic Reactions As mentioned earlier the majority of the various kinds of material inhaled and deposited in the lung cause no tissue reaction Particles larger than 10 μ in size are not found in the deeper parts of the lung but those of smaller size do reach the alveoli where they are engulfed by phagocytes Soluble particles such as marble or gypsum disappear entirely while those less soluble or insoluble particles are carried by the phagocytes to the lymphoid collection of the lung and mediastinum and there deposited Many of the insoluble varieties of dust are inert so far as tissue reaction is concerned and do not cause significant fibrosis The particles of such substances as iron soot etc simply remain in the lymphoid tissue along the course of the lymphatic and blood vessels that accompany the bronchial tree If present in large enough quantities these inert substances may

stimulate sufficient proliferation of fibrous tissue along the lymphatic channels to cause the shadows cast by normal pulmonary vascular markings to be exaggerated as to size density and projection toward the periphery Indeed if the inert material is dense enough—as is iron for example—the concentrated metallic deposits may themselves cause a shadow easily seen in the roentgenogram Although *these inert substances do cause a slight proliferation* of fibrous tissue in their immediate vicinity the reaction is mild and there do not appear to be any recognizable evidences of interference with either the physiologic or immunologic functions of the respiratory apparatus from their retention In contrast to these so called "inert" particulate substances there are others which when inhaled cause definite tissue reaction

PNEUMOCONIOSIS

Pneumoconiosis is a generic term embracing all chronic changes in the lung induced by the prolonged inhalation of dust of a nonliving character with no implication as to the type or severity of the change This definition is so broad that the term *no longer connotes disease The necessity for some* such term is obvious when one realizes that only a few of the inhalable substances truly cause a pulmonary change that results in sufficient dysfunction to warrant the appellation of disease The pneumoconioses of importance to health are silicosis asbestosis coal workers pneumoconiosis (South Wales) pulmonary granulomatosis of beryllium workers Shavers disease and diatomaceous earth pneumoconiosis Of these silicosis asbestosis and coal workers pneumoconiosis (South Wales) have broad socioeconomic implications in addition

Siderosis Siderosis one of the pneumoconioses generally termed benign because it has no demonstrable significance as regards health nevertheless has definite economic implications because its pulmonary radiographic appearance mimics simple silicosis Since it may occur in conjunction with industries which also are known to produce silicosis the differential diagnosis is of considerable importance A detailed history indicating heavy exposure to inhalation of iron oxide rather than free crystalline silica will usually establish the diagnosis When pulmonary nodulation develops in a person who has done welding oxyacetylene cutting of iron or mining of hematite in atmospheres heavily contaminated with crystalline silica particles the differential diagnosis may require lung biopsy

Silicosis Silicosis is a disease of the lungs caused by the prolonged inhalation of fine particles (less than 5 μ) of free crystalline silica (SiO_2) in quantities sufficient to produce the characteristic fibrosis It is manifested clinically by the development of discrete nodules confined to the lung and lymph nodes of the mediastinum *by an increased susceptibility* to tuberculosis and by a paucity of symptoms and signs during the discrete nodular phase of the disease Severe evidences of respiratory embarrassment are likely to develop when conglomerate masses and secondary emphysema develop in the lungs

With the exception of asbestos the various silicates and amorphous silicas produce little or no reaction in the lungs Silicosis therefore is associated only with those pursuits that expose one to the inhalation of naturally occurring or artificially produced forms of free crystalline silica The common form of free silica is quartz which is abundantly distributed in the earth s surface Mining tunneling rock cutting sandblasting abrasive manufacture and use ceramic manufacture foundry work and glass manufacture are among those industries associated in certain jobs with the production or handling of finely divided free crystalline silica Not all jobs or locations in these industries expose the worker to hazardous quantities of silica For example coremakers in most foundries have little exposure to silica whereas the sand *reconditioner or shake out operator may have* considerable If however the coremaker works in a common room he may be exposed to an adjacent silica hazard One can readily understand that an occupational history disclosing only that the occupation was miner or foundryman is entirely inadequate Intimate knowledge of the job working place duration of various jobs and even the actual place in which the work is done is an absolute necessity Anything less is inadequate data on which to evaluate the exposure of a given individual

The silica particles that enter the alveoli and respiratory bronchioles are 10 μ or under Most visible dusts are made up of particles larger than this It has also been shown that silica particles between 5 and 10 μ act only as a foreign body and that the active or fibrogenic component of hazardous silica dust is from 1 to 5 μ Many extremely dusty atmospheres as tested visually are really quite harmless so far as the lung is concerned The reverse may be equally true some very harmful exposures being where there is little visible dust The occupational history must therefore elicit information about particle size as well as about the chemical nature of the dust

It has been amply demonstrated that the total number of particles of hazardous size inhaled is an important consideration in determining the severity of pulmonary injury Contrary to popular belief the black native labor of the South African gold fields has a relatively low incidence of silicosis This is thought to be attributable to the fact that the individual usually works *only 9 to 18* months

underground The whites working in the same areas have a much higher incidence because they are employed on a long term basis

It is obvious from these considerations that the size and concentrations of hazardous particles and the duration of exposure are important determinants of whether or not silicosis will develop in a given individual There is also a factor of individual variation that is related to the effectiveness of the individual's "air filter" and lung cleansing mechanism There is acceptable experimental and clinical evidence to show that when the reticuloendothelial system of the lung is saturated with inert foreign material less than the usual amounts of silica will produce silicosis This has an obvious practical implication

Experience has shown that dusts containing fewer than 5 million particles of free silica 10 μ or less in size per cubic foot will rarely cause silicosis in the normal working span of a man Concentrations above 100 million are considered very unsafe for more than a few months of exposure Under most working conditions of the past it took 10 to 20 years of exposure to produce recognizable silicosis Exceptional circumstances have been reported where unusual exposures of 2 or 3 years duration produced the disease Men exposed approximately a year to high concentrations of virtually pure silica develop a nonnodular change having more the appearance of a chemical pneumonia

In most occupations the inhaled dusts are a mixture of silica and other substances There is no doubt that these accompanying dusts as for example gypsum or iron are capable of modifying the activity of the silica in such a way as to diminish and delay its fibrogenic action In the experimental animal finely divided aluminum hydrate and metallic aluminum have both been shown capable of so modifying the action of silica as to prevent the development of significant fibrosis

After the silica particles reach the alveoli they are picked up by phagocytes These migratory cells carry their engulfed particles to regional lymphoid clusters and to the large nodes of the hilum and mediastinum The actual process whereby the silica particles stimulate cell proliferation and fibrosis is unknown but appears to be a physicochemical process associated with surface phenomena In the areas where the particles accumulate fibroblastic proliferation and hyaline formation produce nodules of a characteristic whorled appearance At first these silicotic nodules are found only in the larger lymph nodes but as lymph drainage becomes progressively more impaired the particles accumulate in the peripheral lymph channels along the course of the blood vessels especially those of the pulmonary artery The tissue reaction in these areas gives the vessels a beaded appearance which can be recognized in a pulmonary roentgenogram but not differentiated from the beading caused by dusts which are entirely free of silica As more and more silica is accumulated in the periphery of the lung the tissue reaction increases to form nodules which alone or by merging with other nodules achieve a size and density sufficient to cast a shadow on the roentgenogram Reconstruction of the nodules in man has demonstrated that they usually form around compress and finally close off a blood vessel of the pulmonary artery tree Around each nodule there is a zone of dilated air spaces described as focal emphysema At this stage the nodules are discrete and comprise a relatively small amount of the total lung tissue The lung between the nodules has a normal appearance This stage of silicosis has been categorized as simple discrete nodular silicosis Some subdivide this group on the basis of the size of the nodules seen in the roentgenogram

In many individuals the reaction does not progress beyond the discrete nodular stage In others large irregular masses of very dense fibrous tissue with irregular radiating strands develop As a rule this occurs in the upper parts of both lungs In advanced stages the entire upper part of both lungs may be a dense shrunken mass of fibrous tissue firmly adherent to the chest wall with the lower parts of the lung the site of severe diffuse emphysema In some instances it appears that these masses form by a shrinking together of the lung and conglomeration of the nodules In others there is little shrinkage but rather an extraordinary proliferation of fibrous tissue When massive or conglomerate shadows appear in the roentgenogram the disease is categorized as complicated or *conglomerate silicosis* Rarely the conglomerate form appears with little or no discoverable accompanying discrete nodulation

Histologic study reveals that in 60 to 70 per cent of those persons exhibiting the conglomerate form of silicosis evidences of tuberculosis can be found associated with the pulmonary masses In the remainder nontuberculous infection may have played a role in causing the intense proliferation of fibrous tissue It seems logical to believe that previous nontuberculous infection may so damage the self cleansing mechanism of the lung that unusual amounts of silica are likely to be retained at the site of previous infections and thus cause unusual fibrotic response in these areas

The diagnosis of silicosis requires that one see nodulation characteristically distributed throughout the lungs in the roentgenogram that other causes of the nodular pattern be ruled out and that a history of exposure to the inhalation of free crystalline silica of particle size and amount capable of causing the nodular fibrosis be obtained These requirements may seem unduly strict in view of the

fact that a histologic stage of the disease must precede the clinical manifestations. The tendency to make a diagnosis of silicosis solely on the basis of a history of exposure to silica is certainly not realistic because in actual practice the majority of persons so exposed never develop clinically significant evidences of the disease. To make the diagnosis on the basis of a positive occupational history and the presence or development of exaggerated bronchovascular shadows will lead to frequent false diagnoses. Many persons who have inhaled nonsilica dust and some with no history of any dust exposure at all will be found to have markedly exaggerated bronchovascular markings. To require nodulation demonstrable by roentgenogram in order to establish a diagnosis is justifiable both from a medicolegal point of view and from that of the person's health since no clinical significance is attached to the prenodular stage of silicosis.

In the simple discrete nodular stage of silicosis there are few related symptoms. Numerous investigators studying silicotic persons from several industries have found only slight evidences of impaired cardiorespiratory function. Many silicotics show entirely normal measurements during this stage. In others there is a moderate reduction of maximal breathing capacity and an absolute increase of residual air. These findings are evidence of slight diffuse obstructive emphysema. When conglomerate masses develop these evidences of emphysema are likely to become more severe and may lead to complete respiratory crippling. In the simple discrete nodular stage there is no impairment of gas diffusion between the atmosphere and pulmonary blood. In the conglomerate stage poor mixing and distribution associated with emphysema lead to a lowered alveolar pO_2 and some degree of arterial hypoxia may develop during exercise. The physiologic abnormalities of conglomerate silicosis are caused primarily by the diffuse obstructive emphysema which accompanies this stage of silicosis. The complaint of exertional dyspnea is due almost entirely to a reduction in the ability to pump air into and out of the lungs. At this stage the clinical symptoms in addition to dyspnea on exertion are cough, expectoration, chest pain and weakness. Cor pulmonale is a late complication and is the cause of death in many instances.

Discrete nodular silicosis appears to be progressive for a year or two after the individual is removed from exposure but then stabilizes and life expectancy appears normal. The conglomerate form progresses slowly even after removal from exposure and life expectancy is diminished.

Tuberculosis is the most feared complication of silicosis. Some individuals having simple discrete nodular silicosis may develop active tuberculosis, the characteristic infiltrates or cavities going through the conventional pattern that eventuates in subsequent spontaneous healing. This combination is best referred to as silicosis *with* tuberculosis and is reported to respond favorably to antibacterial therapy for tuberculosis. More often than not, however, active tuberculosis is prone to pursue one of three courses in the person with silicosis. In the unusual circumstance of a primary or hematogenous infection occurring in lungs already the site of silicosis one finds that the peripheral zone of the silicotic nodule is a preferred site for the development of the tuberculous lesion. Previously sharp borders of the shadow of the nodule in a roentgenogram become blurred and the nodule enlarges. The tuberculous process proceeds with enhanced speed and practically always ends fatally. Reactivation of a preexisting tuberculous focus or the occurrence of exogenous reinfection may lead to rapidly developing cavitation. The disease may then become widely disseminated and will run a rampant and fatal course. In these two types of reaction the tuberculosis is the most prominent feature. Spontaneous recovery is so unusual and the clinical course so adverse that this modification of tuberculosis warrants the designation of silicotuberculosis.

A third combination occurs when silicosis and tuberculosis exist together in such a way as to produce massive fibrosis. The presence of conglomerate shadows in the silicotic person is assumed on statistical grounds to indicate complicating tuberculosis although tuberculosis can be proved in only about 70 per cent of the cases. The silicosis and tuberculosis both are modified to the extent that they produce massive fibrotic conglomerates in which silicotic nodules and the granuloma of tuberculosis can be recognized histologically. Clinically the tuberculosis is modified by becoming very indolent and losing all or most of its invasive and disseminating character. This combination is termed tuberculosilicosis and can exist for many years with few if any symptoms other than cough and dyspnea on exertion.

Anthracosilicosis is a variant caused by the inhalation of a mixture of coal dust and free crystalline silica. In essence its course is very similar to conventional silicosis. It appears that emphysema may develop earlier and be more of a complication in the simple discrete nodular phase in anthracosilicosis.

The type of pathologic process which characterizes silicosis affords little hope of any form of effective treatment for the patient having well established disease. Prevention by adequate control of all dust hazards is the answer to the problem. Aluminum powder has definite prophylactic action in animals and presumably would also be effective in humans unavoidably exposed to silica. No critical

data on this point are available Aluminum by inhalation has been recommended and tried as an agent to relieve the symptoms of silicosis Critical data fail to support its effectiveness except as a form of psychotherapy When active tuberculosis is a complication antimicrobial therapy may be effective in the discrete nodular stage but has little if any influence on the massive conglomerate stage Experience suggests that in the simple discrete nodular stage continued employment is well tolerated It has been argued that in the conglomerate stage physical work is deleterious No critical evidence bears on this important point The silicotic man should of course be protected from any additional silica hazard in the environment

Coal Workers Pneumoconiosis Exposure to the inhalation of coal dust without substantial quantities of silica appears to be rare at least in the United States Because of this and the fact that pure coal dust or carbon inhalation by animals produced no reaction similar to silicosis it has been accepted that the nodulation and conglomerate masses seen in coal miners is in reality a modified form of silicosis Recently the Pneumoconiosis Research Unit of Cardiff South Wales has reported studies strongly suggesting that in the miners of that area pulmonary injury occurs from the inhalation of coal per se rather than from the inhalation of silica Histologic studies show that the earliest change is the deposition of pigment in a stellate shaped discrete macule about which is a zone of emphysema There is a delicate network of reticular fibers in these pigmented areas but characteristically there is no hyaline deposition or extensive fibrosis such as typifies the silicotic nodule These macules with their zone of focal emphysema are numerous and scattered throughout both lungs This stage of the disease is categorized as simple pneumoconiosis of coal workers and is recognized in the roentgenogram by tiny nodulations which may coalesce into larger nodules or mottlings The disease remains at this stage if no further exposure occurs and is characterized by a lack of symptoms Physiologic studies show little or no abnormality of function in spite of the focal emphysema When as happens occasionally a person with evidence of severe emphysema is seen at this stage a nonindustrial or spontaneous origin of the emphysema must be strongly considered

In certain cases of simple pneumoconiosis irregular large localized masses appear and progress in size This stage is termed *progressive massive fibrosis* or *complicated pneumoconiosis* of coal workers This stage is thought to be caused by coexistent infection and tuberculosis is implicated in a high proportion of the cases As the massive fibrosis develops severe obstructive emphysema usually but not always becomes apparent

It is of interest that this entity so closely parallels conventional silicosis differing chiefly in that the focal emphysema is said to be more severe and the degree of fibrosis much less severe in the simple uncomplicated stage of coal workers pneumoconiosis than is true of silicosis Also a high incidence of active tuberculosis and its rapid progression have not been reported in coal workers pneumoconiosis Typical changes have been reported in coal trimmers where silica exposure is considered nonexistent hence the conclusion that they are the result solely of coal dust There is a divergence of incidence in different geographic locations of South Wales and the incidence for South Wales is much higher than in other coal fields of Great Britain

There are no critical studies to demonstrate whether or not this entity exists in other coal mining areas Similar cases both radiographically and histologically are alleged to have been demonstrated in the United States Many questions remain to be studied before the proper meaning of this interesting study from South Wales can be assessed in terms of the coal workers of other areas

Asbestosis The prolonged inhalation of sufficient quantities of asbestos fiber produces a diffuse fibrosis of the lung which may be extremely severe The disease offers a contrast to silicosis in many features Long fibers (20 to 50 μ) rather than short fibers evoke the tissue response the irritant is mechanical rather than chemical the lymphatic system is involved only slightly and late the early lesion being a peribronchial fibrosis the fibrosis is diffuse rather than nodular in character severe pleural changes are common interference with the passage of oxygen from the alveolus to the blood because of thickened alveolar walls is the characteristic physiologic alteration diffuse obstructive emphysema is not manifested clinically or physiologically clinical symptoms and physiologic abnormalities may precede unequivocal roentgenographic evidences of asbestosis there is no alteration of susceptibility to tuberculosis The diseases are similar in that the quantity of proper sized particulates inhaled is the chief determinant of the development of diseases Under usual working conditions years of exposure are required to produce the disease Severe disability (entirely different in fundamental character from that of silicosis) is likely to be present only in advanced cases cor pulmonale though a common cause of death in both is more frequent in asbestosis There is no effective form of treatment for the disease per se

Pulmonary Granulomatosis of Beryllium Workers An unusual chronic granuloma of the lung has been described in persons working where they may be exposed to the inhalation of beryllium and its compounds Although an association with industries using beryllium compounds has been proved the

etiologic factors have not been determined The disease is characterized in the severe form by extreme exertional dyspnea paroxysmal cough marked loss of weight and cyanosis the roentgenogram shows a diffuse ground glass appearance of the lungs plus enlargement of the hilar lymph nodes Interference with diffusion of oxygen across the alveolar membrane is the underlying physiologic defect and cor pulmonale the usual cause of death Minute exposures to the chemical and delay of months to years between exposure and onset of the disease make this a most bizarre entity The disease has more than just industrial implications since bona fide cases have developed following the inhalation of exceedingly minute quantities of beryllium under nonindustrial circumstances The number of cases is increasing Differential diagnosis from other nodular granulomas is at times most difficult No authentic spontaneous complete recovery has been reported The mortality rate is high but many persons remain in an arrested state of the disease for years ACTH and cortisone have produced dramatic but not permanent remissions

Section 5 The Alimentary Tract

241 DIAGNOSTIC CONSIDERATIONS

Thomas E. Machella

The more important manifestations of disorders of the alimentary tract have already been discussed. They include dysphagia (p. 127), indigestion (p. 118), constipation (p. 132), diarrhea (p. 132), and ileus (p. 45). The section to follow will deal with the alimentary disorders from the standpoint of specific diseases rather than symptoms. Before discussing these specific diseases, certain general principles will be considered.

FUNCTIONAL DISORDERS OF THE GASTROINTESTINAL TRACT

No attempt will be made to discuss functional disorders of the gastrointestinal tract in detail. It must be pointed out, however, that such disorders, especially of the motor functions, exist and that they are very frequently responsible for gastrointestinal complaints. Functional motor disturbances which may be associated with definite symptoms include esophagospasm, cardiospasm, gastric hypo- and hypermotility, spasm of the pylorus, spasm of the gastric antrum, spasm of the first and second portions of the duodenum, very rapid or delayed gastric emptying, duodenal stasis, small intestinal hyper- or hypomotility, and various spastic and atonic states of the colon. Secretory disturbances of significance are those of excessive secretion of highly acid juice by the stomach and of mucus by the colon. Though a temporary functional gastrointestinal disturbance may occur in a healthy person under the influence of an emotional upheaval, more prolonged and severe changes in gastrointestinal functions on an emotional basis may lead to actual morphologic changes in the gastrointestinal tract, depending not only on the nature, intensity, and duration of the emotional stimuli but also on the relative influences of the two effector divisions of the autonomous nervous system and the susceptibility of various portions of the gastrointestinal tract. Examples of actual organic changes on the basis of emotional disturbances, in the opinion of this writer, include peptic ulcer, chronic gastritis, duodenitis, ulcerative colitis, regional enteritis, and megaesophagus on the basis of cardiospasm. These diseases occur in those who are high strung and hypersusceptible reactors to stimuli when they are subjected to a variety of emotional frustrations and insults. The successful medical management of such patients calls for a sincere, understanding, helpful, and sympathetic attitude on the part of the physician, combined with an ability to instill confidence and hope. Induction of remissions and reduction in the incidence of relapses depend on the discovery and successful solution of the emotional problems responsible. Usually a good doctor can handle such problems satisfactorily, but occasionally expert psychiatric aid may be required.

It is also important to recognize functional disturbances of the gastrointestinal tract which are nonpsychogenic in origin but are secondary to primary disorders of other organs and systems such as diseases of the gallbladder, liver, pancreas, heart, kidneys, pelvic organs, endocrine glands, and the nervous system. In addition, metabolic and deficiency diseases, allergic states, and infectious and toxic conditions may give rise to functional gastrointestinal disorders.

ROENTGENOLOGY OF THE GASTROINTESTINAL TRACT

Roentgen examination is the most important laboratory aid in the diagnosis of disorders of the gastrointestinal tract. It should be performed not only in every patient in whom an organic lesion of the alimentary tract is suspected but also in those in whom functional disorders are to be detected. The various roentgen techniques include a survey film, barium meal occasionally supplemented by the insufflation of air into the stomach, small intestinal enema, special intubation techniques, and the barium water enema and barium air contrast examination of the colon.

Survey Film. A preliminary or survey film of the abdomen may sometimes furnish useful information in a variety of conditions which give rise to gastrointestinal symptoms. It may aid in the localization of calcific deposits in the pancreas, gallbladder, kidneys, mesenteric lymph nodes, and other abdominal and pelvic structures as well as in calling attention to the presence of radiopaque foreign bodies in the abdomen or the possibility of mesenteric vascular occlusion. It is useful in confirming the presence of free fluid when physical signs are not clear, and in localizing masses involving retroperitoneal structures which interfere with the clarity

of the shadows of the iliopsoas muscles. When intestinal obstruction is suspected *preliminary films* of the abdomen should be made with the patient in both the recumbent and upright positions and the films should be examined promptly for *evidence of* air or air fluid levels in the intestinal loops. Thus information not only as to the diagnosis but also as to the location of the distended loops and the site of obstruction is obtained. A survey film of the abdomen should also be made when *perforation of* a viscus is suspected. In such cases a collection of air may be found in the uppermost portion of the abdomen depending on the position of the body when examined with the beam of roentgen rays horizontal or at the site of the perforation if the latter is walled off by exudate or adhesions. The survey film is usually of no value in identifying or localizing nonobstructing lesions which involve the mucosa of the gastrointestinal tract. For this purpose a *contrast* medium is essential. Rarely an irregularity in the outline of the collection of air in the fundus of the stomach (*magenblase*) detected *in a plain film* of the abdomen or of the chest has furnished a clue to the presence of a carcinoma in *this region*.

Barium Meal. In the absence of evidence of *intestinal* obstruction or of a perforated viscus and *if the* patient is not vomiting one can proceed in most instances with the administration of a barium *meal* by mouth for the purpose of examining the esophagus stomach duodenum and small intestine and obtaining certain types of information concerning the colon. The behavior of a water barium meal and when indicated of physiologic meals containing barium should be observed fluoroscopically because the final solution of diagnostic problems often depends on a careful fluoroscopic examination. Much information can thus be obtained about the functional behavior of alimentary structures which it is not possible to get from roentgenograms. This is especially true in the detection of functional motor disturbances referred to earlier. It is important to realize however that fluoroscopic examinations vary in their reliability depending on the expertness of the observer and the care exercised by him in performing the examination. The exposure of a film offers the advantage of a permanent visual record of the lesion at any one time. The use of spot and pressure film devices is of value in the many instances when information concerning mucosal relief is desired.

If the clinical manifestations point to an obstructing or ulcerating lesion in the esophagus or stomach roentgen examination should precede passage of a tube or endoscopy as the risk of the former examination is less. It should also initiate the diagnostic survey of all patients who have recently recovered from a gastric or duodenal hemorrhage. The roentgen examination of the esophagus using capsules filled with barium and *thick and thin liquid* barium mixtures is useful in the demonstration of cardiospasm esophageal *tumors* diverticulum or ulcer hiatus hernia esophageal varices *or stricture* and nonopaque foreign bodies and to outline extrinsic mediastinal masses.

In the stomach study of the barium meal may reveal ulcer cancer polyps hypertrophic gastritis *tumors of* adjacent regions gastrojejunal ulcer and foreign bodies. *It is also useful in* detecting functional disturbances of the stomach in that it supplies information on the *characteristics of peristalsis and* tonus as well as on the *emptying time*. *Patients* with gastric ulcer under medical management should be reexamined at *the end of 3 weeks*. Persistent ulcerative lesions may require surgical intervention to rule out the *possibility of gastric* carcinoma. Lesions of the fundus of the stomach are more apt to be overlooked than those elsewhere in the stomach because of the inaccessibility of this area to palpation. The barium meal is of little value in the diagnosis of many forms of gastritis but may suggest the existence of a chronic superficial or hypertrophic gastritis. The demonstration of changes in the mucosa of the duodenal cap in cases of chronic gastritis is valuable additional evidence of the presence of gastritis. Such studies require careful evaluation of the character of the mucosal relief.

Air introduced by means of a tube is sometimes used for a contrast in the examination of the stomach. A double contrast picture may be obtained by administering a small amount of barium. This type of examination is especially useful in demonstrating polypoid tumors as well as pressure defects produced by extragastric lesions.

Fluoroscopic and roentgenographic studies of the behavior of a barium meal are of value in the diagnosis of lesions of the small intestine in the demonstration of disease in neighboring structures causing persistent displacement of a loop or loops of intestine and in revealing abnormalities in the mucosal pattern and motility. The examination of the small intestine however presents difficulties because of the overlapping loops. The duodenum and the terminal ileum are the only two segments which can be examined satisfactorily. The rapid transit of the barium meal necessitates frequent roentgen examinations. The barium should enter the cecum within 3 hr; any delay should cause suspicion. The normal mucosal pattern varies but it is affected by many factors such as emotional disturbances drugs deficiency disease inflammation adhesions constipation obstructions and neoplasms.

The study of the colon on the second day after a barium meal is not ess[illegible]

of a patient suspected of having colonic disease because it is impossible to fill the colon completely and, therefore many colonic lesions cannot be demonstrated satisfactorily The procedure however can furnish information concerning the position and functional state of the colon which may not be so satisfactorily obtained by barium enema alone It is of special value in the diagnosis of spastic colon When it is used for this purpose antispasmodics should be withheld

Small intestinal Enema Examination of the small intestine following intubation of the duodenum and the continuous gravity introduction of 500 to 1000 ml of a thin barium mixture offers many advantages in the study of the small intestine and in the diagnosis of obscure lesions The procedure permits an orderly filling of the loops from above downward and a demonstration of the entire small intestine The head of the barium column should reach the cecum in about 15 min

Intestinal Intubation The roentgen examination using the double-lumen Miller Abbott or similar tube can supply valuable information concerning small intestinal lesions and disorders Normally about 3 hr is required for the balloon to pass through the intestine into the cecum When the balloon fails to advance in 3 to 4 hr a lesion may be suspected providing sufficient slack of the gastric portion of the tube has been allowed If the inflated balloon enters the cecum an obstructing lesion of the small intestine is usually eliminated In paralytic ileus the rate of passage of the balloon is much slower than in mechanical ileus After deflation of the balloon the injection of 30 to 40 ml of a thin barium mixture at the point of its arrest may demonstrate clearly the site and the nature of the lesion causing the obstruction The barium should be withdrawn promptly after the examination is completed If surgery is decided on the tube is left in place as a guide to the point of obstruction as well as for the purpose of deflating the bowel during the postoperative period

Barium Enema The introduction of an opaque medium into the colon through the rectum is necessary in the diagnosis of organic disease of the colon For this purpose a mixture of water and barium is most commonly used The procedure is useful in demonstrating colonic tumors granulomas diverticulosis ulcerative colitis megacolon and extracolonic intraabdominal masses It is also of value in studying the terminal ileum The examination should not be relied upon to exclude lesions of the colon distal to the lower sigmoid and lesions of the rectum Diseases of these areas are best detected by proctosigmoidoscopy Small lesions involving the flexures of the colon unless carefully searched for may be readily overlooked Conditions which may contraindicate the performance of a barium enema include a painful anal fissure a tight rectal stricture in the absence of a colostomy suspected appendicitis and any acute illness in which the preparation for and the performance of the enema would prove exhausting to the patient

Barium Air Double-contrast Enema The diagnostic value of the roentgen examination of the colon may be enhanced by the introduction of air after evacuation of most of the barium The contrast furnished by the air and the barium adhering to the lumen of the bowel reveals the character of the mucosal relief Small polyps and carcinomas not seen on the usual barium enema films may be demonstrated by this method Great care and at times repeated examinations are necessary in interpreting films as retained fecal masses may be very confusing and may simulate the appearance of polyps

Roentgen examination of the gastrointestinal tract is not an infallible procedure Lesions may be missed even by those with great skill and much experience Consequently when the clinical evidence indicates the possibility of serious disease and the roentgen study is negative the examination should be repeated The need for multiple or repeat examinations to discover an early carcinoma of the stomach or a polyp of the colon is not generally appreciated

OTHER DIAGNOSTIC METHODS

Endoscopy as well as methods such as liver function tests and other procedures will be discussed in context.

242 DISEASES OF THE MOUTH

Thomas E Machella

Careful inspection of the mouth often yields important information Aside from the signs of various local diseases of the oral structures which

will not be discussed in this book significant evidence of systemic disturbances is often encountered Of the disorders which frequently produce abnormalities in the mouth the following are especially important

Disturbances of Fluid Balance These have been discussed in some detail in Chap 48 Dryness of the mucous membrane and a longitudinal wrinkling of the tongue are likely to be indications of water deficit and extracellular fluid deficit respectively Dryness of the mucous membranes may also be encountered in mouth breathers or constant talkers and as a part of the idiopathic state known as *Sjogren s syndrome* Increased salivation or ptyalism may be observed in patients with excess fluid intestinal parasites mercury poisoning postencephalitic form of parkinsonism scurvy hyperchlorhydria iodism and cretinism

Hematopoietic Disorders Pallor of the mucous membranes is a better index of anemia than is pallor of the skin Atrophy of the papillae of the tongue with loss of the characteristic dorsal granularity is observed in most patients with pernicious anemia and in occasional instances of chronic hypochromic anemia A bright red sore tongue may be seen in pernicious anemia A deep maroon color instead of the normal reddish pink of the oral surfaces is typical of polycythemic disorders Hemorrhagic spots on the palate and cheeks are common in the more severe thrombocytopenic purpuras both primary and secondary Edema swelling and often ulceration and necrosis of the gum may occur in acute leukemia and there may be a hypertrophic gingival reaction These are readily differentiated from the hypertrophy of the gums following prolonged use of Dilantin (diphenylhydantoin sodium) for epilepsy Pain marginal necrosis and bleeding are absent in the latter Necrotic ulcerative irregular shaped sores of the mouth and pharynx may be found in cases of granulocytopenia

Nutritional Disorders The tongue is characteristically deep red (beefy) in patients with pellagra and in many patients with sprue as a result of a deficiency of one or more members of the vitamin B complex such as nicotinic acid or riboflavin A superficial glossitis may also accompany a chronic iron deficiency anemia with or without other manifestations of the Plummer Vinson syndrome Spongy swollen and purple-red gums which bleed readily are observed in advanced scurvy provided the patient has natural teeth

Endocrine and Metabolic Disorders Bronze colored spots of pigmentation on the buccal mucous membrane of the cheeks and palate are suggestive of Addison s disease although somewhat similar areas may be seen in patients with hemochromatosis The tongue is likely to be large and in persons with myxedema Macroglossia may also be observed in acromegaly and in primary systemic amyloidosis Soreness and burning of the tongue without obvious change in appearance may be a manifestation of diabetes though actual lesions of the gums and tongue are not uncommonly found in diabetic patients because of the predisposition to infection Recurring or cyclic ulcerative stomatitis in association with vulvitis ascribed to ovarian dysfunction has responded to gonadotropin administration Similar changes in the mouth may occur in erythema multiforme

Metallic Poisoning Granular black pigmentation of the gums at the points of insertion of the teeth and diffuse reddening of the oral mucous membranes with profuse salivation are suggestive of intoxication with lead and mercury respectively A stomatitis and gingivitis with bluish pigmentation may be observed in patients receiving bismuth therapy and a gingivitis from exposure to chromium Dryness of the mouth may be complained of in zinc poisoning

Other Disorders Numerous alterations of the oral cavity may occur Among the more characteristic are the strawberry tongue" of scarlet fever the Koplik spots of measles the membranous patches of diphtheria the vesicles of smallpox and chickenpox the heavily coated tremulous tongue of typhoid fever the chancre of primary syphilis the mucous patches of secondary syphilis and the bald tongue of tertiary syphilis Also to be borne in mind are the aphthous ulcers and swollen bleeding gums of herpes simplex and the papular vesicular and ulcerative lesions of herpangina Ulcers in the mouth are a very common presenting lesion in histoplasmosis Less commonly encountered are such miscellaneous infections as blastomycosis leprosy leishmaniasis and lymphogranuloma venereum Stomatitis occurs in uremia and following the administration of broad spectrum antibiotics especially chloramphenicol Hairy tongue often follows the use of penicillin lozenges Any indolent lesion in the mouth merits biopsy to rule out malignancy

243 DISEASES OF THE ESOPHAGUS

Franz J Ingelfinger

Although the anatomy of the swallowing tube is still controversial the structural definitions indicated in Fig 170A are used in this discussion The esophagus proper with principally propulsive functions is regarded as lying between two sphincteric segments at its upper and lower ends The upper

segment comprises the cricopharyngeus muscle and the highest circular muscles of the esophagus The lower sphincteric mechanism is considered to depend on a zone including the inferior esophageal sphincter and a portion of the vestibule It normally remains closed except during swallowing or regurgitation and with the diaphragm is instrumental in preventing gastric reflux.

Symptomatology ***Dysphagia*** Although esophageal disease accounts for no more than one tenth of all gastrointestinal complaints it is characterized by one of the most specific symptoms in medicine the sensation of food sticking on its way from the mouth to the stomach This dysphagia of esophageal origin must be clearly distinguished from the swallowing difficulties caused by inability to expel material from the oropharynx into the esophagus Esophageal dysphagia since it occurs only with swallowing also differs from the persistent sensation of globus hystericus Esophageal dysphagia may be painless more often it is distressing and sometimes it causes pain of alarming proportions Whatever its concomitants the complaint of food sticking somewhere behind the sternum signifies that some process—whether functional spasm or organic stricture—is occluding the esophageal lumen

The level of the sticking sensation, corresponding to the most frequent site of esophageal disease is usually under the lower end of the sternum In other instances dysphagia is localized higher in the chest or at the base of the neck either because the responsible lesion is situated higher or because sensations from the distal esophagus are referred to the sternal notch by approximately one fourth of adult patients

Dysphagia occasionally begins abruptly and reaches maximum intensity at the onset but more commonly it appears gradually in intermittent attacks precipitated by the ingestion of certain foods Beef and fresh bread are notorious offenders probably because these elastic solids are wedged by peristalsis into the esophageal area narrowed by disease If this happens the patient may be able to force the offending morsel past the obstructing point by rapidly gulping water With progressive disease however the swallowing of liquid as well as solid becomes difficult. Liquids of low viscosity as a matter of fact, are regurgitated too readily and the peristaltic action of the esophagus is used to best advantage when the patient takes food of pultaceous consistency

Pain. Pain, a common symptom of esophageal disease may be persistent and unrelated to swallowing or intermittent and intimately associated with dysphagia often it is precipitated by the ingestion of acid, spicy carbonated very cold, or very hot substances The mechanisms underlying esophageal pain are two (1) ulceration or inflammation of the mucosa and (2) increased intramural tension produced by violent peristalsis or stationary muscular spasm Esophageal pain is usually felt anteriorally under the sternum at a level corresponding to the position of the lesion but it may also be referred to the upper back the neck the jaws and into both arms particularly their inner aspects Anatomically and functionally therefore the transmission and reference of pain from the esophagus and from the heart may be the same

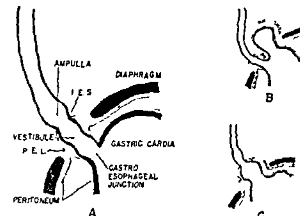

Fig 1?0 Diagrammatic representation of the structure and relations of the lower esophagus A Normal esophagus B Parahiatal hernia C Sliding hernia In this type of hernia the distinction between the vestibule and the herniated cardia is lost I E S = Inferior esophageal sphincter P E L = Phrenoesophageal ligament (*Modified from Lerche Allison and Sweet*)

Heartburn Heartburn pyrosis and water brash mean different things to different people and it is important to determine what *heartburn* signifies to the patient with this complaint Here the term *heartburn* is used to denote an intermittent symptom complex which begins with a burning, tight sensation under the sternum and then travels upwards wavelike to reach its scalding, acid maximum in the neck or throat Salivation is often part of the picture The cause of heartburn may be muscular spasm reflux of gastric contents or both but its exact pathogenesis is still uncertain.

Belching Many a belch is forceful regurgitation of air that has been sucked or swallowed into the esophageal lumen Although belching, therefore is frequently an esophageal phenomenon it is except in diaphragmatic hernia, not a common manifestation of esophageal disease More often it is a functional disorder or is indicative of gastric or cardiac disease

Regurgitation. Regurgitation, as opposed to vomiting, means the effortless appearance of esophageal or gastric contents in the mouth A functional disorder of esophageal motility a retrograde

flow of material forced by normal esophageal peristalsis against a stenotic area or as in the case of the dilated esophagus of cardiospasm a gravitational effect may be responsible for regurgitation

CANCER

Symptoms The importance of dysphagia as a symptom and the urgent necessity of determining its cause are no better exemplified than by the patient with esophageal cancer Difficulty in swallowing is often the patient s first and at times his only complaint as the growth encroaches upon the lumen Although intermittent initially the dysphagia is inexorably progressive over the course of months In fungating tumors the commonest gross variety of esophageal cancer pain under the sternum in the back or in the neck makes its appearance sooner or later In some cases an early symptom not to be ignored is substernal burning on swallowing hot liquids Slow oozing of blood is a frequent complication and brisk bleeding a rare one In about 25 per cent of cases however particularly with infiltrative or polypoid cancers symptoms other than dysphagia appear only terminally When esophageal stenosis is severe regurgitation of esophageal contents sometimes blood flecked is common

Approximately 20 per cent of esophageal cancers are in the upper third 30 per cent in the middle and 50 per cent in the lower third of the organ The lesions in the upper two thirds are derived from squamous esophageal mucosa In the distal esophagus over half the cases prove to be adenocarcinomas indicating that many cancers in this area are gastric in origin A gastric origin is as a matter of fact often evident on operation in cases which radiologically appear to be purely esophageal

Course Physical examination is usually negative and even those in an advanced state may present no more than the signs of malnutrition Although metastases to lymph nodes occur in three fourths of the cases only 5 per cent have palpable nodes in the supraclavicular or other accessible areas Since the liver and lung are each involved eventually in 20 to 25 per cent of the cases hepatomegaly or pulmonary lesions may be evident Other organs subject to metastatic foci are bone kidneys and adrenal gland Sometimes direct invasion of adjoining structures leads to dramatic complications (1) mediastinitis with subcutaneous emphysema in the neck (2) tracheo or bronchoesophageal fistula with an apoplectic cough induced by swallowing liquids or (3) aortic perforation with precipitous exsanguination

Diagnosis Esophageal cancer occurs in the usual cancer age groups and males preponderate four to one It is about one tenth as common as cancer of the stomach in either sex X ray often reveals the irregular and sometimes surprisingly long luminal defect caused by esophageal cancer but other invaluable information is provided by esophagoscopy and biopsy The initial examination with either procedure is not however invariably adequate in differentiating cancer from inflammatory stricture Cytologic examination of material obtained by esophageal lavage is proving remarkably helpful

Treatment Intensive deep radiotherapy such as has been made available by high voltage x ray apparatus and Co^{60} bombs is achieving some palliative success but lesions that appear to be resectable are usually treated surgically Calculated on the basis of all esophageal cancer patients who enter a hospital the 5 year cure rate is still a disappointing 0 to 7 per cent In some hands however 5 year cure rates in patients who at operation have no gross evidence of extension are over 30 per cent for cancers in the lower third of the esophagus Successful resection of higher cancers is more difficult

DIAPHRAGMATIC HERNIA

A common abnormality affecting the esophagus but strictly speaking of gastric origin is herniation of the stomach through the esophageal hiatus of the diaphragm Two types of hernia are described In one the paraesophageal or parahiatal type the gastric cardia slips through the muscular aperture beside a normally situated gastroesophageal junction still encircled by the fibrous components (the phrenoesophageal ligament) of the hiatus (Fig 170B) In the other the sliding or short-esophagus type the stomach slides through both the membranous and muscular openings thereby placing the gastroesophageal junction above the diaphragm (Fig 170C) This position of the junction makes the esophagus appear shortened and actual shortening may be caused by chronic esophageal inflammation A congenitally short esophagus however is very rare

The incidence of diaphragmatic hernia is debated since its radiologic differentiation from a prominent vestibule is a matter of individual interpretation In elderly people however the incidence may be as high as 33 per cent and stocky obese patients are particularly susceptible The relative prevalence of the two types of herniation is also uncertain but symptoms arise more commonly from the sliding type

Symptoms Both parahiatal and sliding hernias may give rise to symptoms when the herniated pouch is irritated or injured by the mechanical disadvantages of its position or when it is sufficiently large to affect adjoining viscera These complications appear to be especially prevalent in women

The most common complaint is high epigastric or low midthoracic pressure or a pain which may radiate along the left costal margin to the top of the left shoulder or down the arms. Belching is copious and hiccoughing occasional. By and large the symptoms are moderately distressing but a rare case may suffer acute prostration should strangulation of the herniated stomach take place. If the mucosa of the hernia becomes eroded acute or chronic blood loss is possible but the importance of diaphragmatic hernia as a source of gastrointestinal blood loss is usually exaggerated. Large hernias rarely cause intermittent acute dysphagia by angulating, twisting or compressing the esophagus or they may sufficiently displace the lungs or heart to cause cardiorespiratory symptoms. Whatever the clinical manifestations of diaphragmatic hernia they are characteristically precipitated by eating and aggravated by lying down both of which actions tend to force more of the stomach into the thoracic cavity.

The principal complication affecting sliding diaphragmatic hernias is peptic esophagitis. This is discussed below.

Diagnosis. Diagnosis is made by radiologic means. Once a diaphragmatic hernia is radiologically identified however its relation to the patient's symptoms poses a nice problem. On one hand the symptoms of diaphragmatic hernia are so diverse that they may resemble the symptoms of coronary insufficiency, biliary colic, pancreatitis, gastric or duodenal ulcers, esophageal diseases (Table 122) or functional digestive disorders. On the other hand, diaphragmatic hernias are diagnosed so frequently by the radiologist that many hernias must be considered as incidental findings unrelated to the patient's complaints. As a rule upper abdominal or lower thoracic symptoms should not be ascribed to a radiologically demonstrated diaphragmatic hernia unless (1) other possible causes are excluded with reasonable certainty and (2) some evidence exists that the symptoms are intensified when the patient eats or lies down. A particularly difficult problem in differential diagnosis is substernal distress in the elderly patient with both electrocardiographic abnormalities and diaphragmatic hernia. Although coronary pain is usually related to exercise and that of hernia precipitated by lying down these associations are not constant and both conditions may be aggravated by a full meal. When the evidence is conflicting the wiser course is to assume that coronary disease is the principal offender.

Treatment. Most patients can become fairly comfortable but not entirely symptom free by eating small meals of low fat content (fat retards gastric evacuation) by avoiding food entirely for 3 hr before going to bed and by sleeping with the upper half of the body elevated. Additional symptomatic relief may be afforded by sedatives and antispasmodics. With respect to surgery sliding hernias with esophagitis present a special problem but the approach to paraesophageal hernias should be extremely conservative. Operative repair of these hernias is not indicated unless they have been identified unquestionably as causing intermittent esophageal obstruction, respiratory disease, perforation, strangulation, bleeding or severe distress not affected by intensive use of medical measures. In some cases major surgery can be avoided and symptoms lessened by crushing the left phrenic nerve to paralyze the left diaphragm.

ACUTE ESOPHAGITIS

Acute esophagitis in a mild form with substernal pain aggravated by swallowing may complicate upper respiratory infections. More violent forms with variable necrosis may occur in moribund states, in diseases of the central nervous system, after extensive burns or trauma, after operations especially if vomiting is pronounced or gastric intubation prolonged, and with specific infections such as scarlet fever, diphtheria and typhoid. In many of these conditions ischemia, the trauma of vomiting and exposure of the esophageal mucosa to acid gastric contents must be important pathogenic factors.

The ingestion of corrosive agents produces a classic variety of acute esophagitis which if not immediately fatal commonly terminates in extensive esophageal stenosis.

CHRONIC ESOPHAGITIS

Chronic esophagitis is an inflammatory reaction of the esophageal wall with erosions or frank ulceration of the mucosa and narrowing of the lumen by muscular spasm and fibrotic stricture. This chronic disorder has been reported as a sequel to acute esophagitis as a complication of systemic or local diseases and as a late radiation effect but from the long list of heterogeneous and often obscure causes reflux of gastric contents is probably the most significant.

Peptic esophagitis and the acid peptic factor appear to be causally related since this form of chronic esophagitis occurs predominantly in males and over one third of the cases have or have had duodenal ulcer. In addition patients affected have a sliding diaphragmatic hernia or a history of prolonged gastric intubation or vomiting, circumstances suggesting that the acid peptic factor gains access to the esophagus because normal mechanisms preventing gastric reflux are impaired. In some adults and more commonly in infants or children severe

Table 12? DIFFERENTIAL DIAGNOSIS OF ESOPHAGEAL DISORDERS

Disorder	Symptoms (in order of incidence)	Dysphagia		Blood loss	X-ray	Esophagoscopy	
		Chronology of development	Sensation of food working through obstructed area			Insertion of instrument past narrowed area	Purpose and significance
Cancer	1 Dysphagia 2 Pain—70% of cases	Weeks to months	Yes (early in course)	Intermittent oozing common Brisk bleeding rare	Normal peristalsis Mild dilatation Irregular defect Diaphragm Gastric cardia	Difficult or impossible	Essential examination for inspection and biopsy in all suspicious cases. Not indicated when x-ray diagnosis of cancer appears unequivocal since risk of procedure unnecessary
Diaphragmatic hernia (paraesophageal)	1 Epigastric or substernal pressure 2 Belching 3 Intermittent attacks of pain 4 Dysphagia either absent or occurs in rare and transient attacks	Months to years	No	Alleged common cause of acute and chronic bleeding, but incidence exaggerated	Normal esophagus except for displacement by Herniated stomach Diaphragm	Readily accomplished	Little additional information obtained
Peptic esophagitis	1 Heartburn 2 Substernal pain after cold, hot, spicy, and acid food 3 Dysphagia 4 History of peptic ulcer—30% of cases	Months to years	Yes	Hemorrhage occur but unusual	Dilatation absent to moderate Funnel-shaped narrowing of stricture Possible ulcer niche Sliding gastric hernia	Difficult or impossible	Important examination to evaluate esophagitis and exclude cancer. Frequently used as ancillary procedure in dilatation of stricture
Cardiospasm	1 Dysphagia 2 Occasional attacks of pain 3 Regurgitation 4 Chronic cough	Years	Infrequent	None except after operative procedure leading to secondary esophagitis	Dilated esophagus Irregular uncoordinated contraction Beak-shaped narrowing produced by achalasia of vestibule	Surprisingly easy except in case with such massive esophageal dilatation that the distal lumen cannot be identified	Helpful to evaluate secondary esophagitis and to carry out dilating procedure

peptic esophagitis may be related to abnormal extension of gastric mucosa into the esophagus

Symptoms The patient may or may not have had a past history of duodenal ulcer but almost invariably he has been a long sufferer from heartburn At first this symptom troubles the patient only after dietary indiscretions soon after retiring to bed, or when bending over Intermittently and progressively however the heartburn worsens cold and hot foods and slightly acid foods are increasingly painful to swallow and eventually dysphagia appears With advancing disease malnutrition is inevitable and slow blood loss occasional

Diagnosis Diagnosis is made principally by x ray which in cases with stricture shows a gradual and funnel shaped narrowing of the distal esophagus The esophagus appears shortened and terminates in a tentlike supradiaphragmatic projection of the stomach characteristic of a sliding hernia The differential diagnosis is outlined in Table 122 but examination of cells obtained by biopsy esophageal washings, or both is essential

Treatment Medical treatment has a twofold aim reduction of gastric acidity and prevention of gastric reflux. To these ends the patient should observe an intensive ulcer regimen modified to the extent that he should avoid foods (but not antacids) after the evening meal and should sleep with the upper half of his body elevated Anticholinergics may be helpful at bedtime to reduce nocturnal gastric secretion, but they are best avoided during the day since anticholinergics increase gastric retention and reduce the gastric secretory response to meals but little Medical management may relieve dysphagia produced by spasm but it is relatively ineffective when the cause is a well-defined stricture This is treated by cautious dilatation

If dysphagia persists or recurs in spite of medical treatment surgical intervention is indicated In an early case repair of the sliding hernia may be sufficient but in most instances some type of operation designed to reduce gastric acidity (subtotal gastrectomy vagotomy *with* a drainage procedure) is carried out at the same time Such surgical effort is unfortunately not much more than 75 per cent successful Resection of the involved area as may be necessitated by uncontrollable stenosis is also not too rewarding since all barriers to gastric reflux are removed recurrence of esophagitis proximal to the gastroesophageal anastomosis is likely Some surgeons are trying to overcome this difficulty by replacing the resected esophageal section with a segment of small intestine

PEPTIC ULCER

A solitary peptic ulcer is occasionally found in the distal esophagus This lesion differs from peptic esophagitis in that the ulcer is more sharply localized penetrates more deeply and is more apt to perforate or to cause massive bleeding On the other hand the ulcer is more susceptible to standard medical antacid management (Chap 245) produces less extensive stricture on healing and causes less chronic dysphagia than peptic esophagitis The solitary peptic ulcer in the distal esophagus thus resembles a benign gastric ulcer in many respects Indeed many ulcers at the lower end of the gullet actually involve either a herniated portion of stomach or a section of the esophagus—perhaps the vestibule—that is lined with gastric mucosa

CARDIOSPASM

The term *cardiospasm* does not describe the nature of the disorder accurately but is well established by custom Actually cardiospasm is a motor disorder involving the entire distal two thirds of the esophagus In the esophagus above the vestibule the normal propulsive pattern of peristalsis is replaced by nonprogressive and uncoordinated contractions For this reason the name *aperistalsis* is used in Brazil The massive esophageal dilatation seen in some cases has in turn given rise to the name *megaesophagus* Finally the term *achalasia* (literally "not relaxation") is popular because the lower esophageal sphincter i e the vestibular area does not relax normally in response to swallowing and thus creates an obstructing segment at the distal end of the esophagus

The motor disorders of cardiospasm appear to reflect an impaired cholinergic innervation of the esophagus Histologically the cells of the myenteric plexus i e the parasympathetic ganglions are damaged or absent Pharmacologic studies have shown that administration of a cholinergic agent produces a tetanic specific and often violent contraction of the affected esophagus This response when interpreted in the light of Cannon s finding that denervated structures respond maximally to neurohumoral stimulation provides additional evidence that the cholinergic innervation of the esophagus is deficient in cardiospasm The ultimate etiology however is unknown

Symptoms Cardiospasm affects all ages of both sexes Its course is usually chronic with dysphagia gradually worsening over months to years In some patients the process is painless in others spasms of substernal pain may follow eating Occasionally the initial episode of dysphagia appears with dramatic suddenness either after bolting food or after an emotional upset In either case however the condition has probably been present in latent form before the acute episode As the disease progresses extreme and tortuous dilatation of the esophagus may develop When the patient lies down the

copious amount of food residue saliva and other secretions contained in the spacious esophageal sac runs freely back into the pharynx and mouth If the regurgitated material is aspirated chronic infection of the lung bases is a potential complication Stagnation of food also leads to a chronic inflammatory reaction of the esophageal mucosa and submucosa Obviously weight loss is common

Diagnosis Diagnosis is usually made without difficulty on the basis of the history and the characteristic radiologic findings of abnormal esophageal motor function with a smooth beaklike narrowing of the distal esophageal segment (Table 122) In some cases cancer originating in the gastric cardia but infiltrating the esophagus may present a somewhat similar x ray appearance and a variety of motor disorders of the lower esophagus has been confused with cardiospasm These problems in differential diagnosis should be less frequent if it is remembered that the radiologic abnormalities of cardiospasm consist of deranged peristalsis as well as narrowing in the area of the vestibule

Treatment Medical treatment symptomatic at best consists of the use of sedatives and bland semisolid foods warmed to body temperature Smooth muscle relaxants such as nitrites are often used to open the vestibule but the effect is too transient to permit the patient to enjoy a meal Anticholinergics may lessen oral and esophageal secretions and may inhibit painful spasms in view of the basic neurologic defect however they potentiate rather than alleviate the dysphagia The best available therapy is forceful dilatation of the narrowed vestibule with the specific purpose of tearing some of the muscle fibers in this area Passing graduated mercury tipped bougies does not accomplish this and therefore relieves dysphagia only briefly It is necessary to use bags that can be inflated under pressure or a mechanical (Starck) dilator In experienced hands these instruments when positioned under fluoroscopic control rarely cause complete esophageal rupture and dysphagia is relieved successfully for years or even permanently in over 75 per cent of cases Forceful dilatation does not restore normal esophageal motility but it impairs the contractile power of the vestibule and thus permits the esophagus to empty under the influence of hydrostatic and transmitted oropharyngeal pressures Improved esophageal emptying in turn prevents further esophagitis and distention of the lumen

When the esophagus is extremely dilated and sufficiently tortuous to warrant the adjective *sigmoid* mechanical dilatation of the narrowed area is often not feasible Surgery is then necessary Unfortunately any procedure that creates a new opening between the dilated esophagus and the stomach permits when the patient lies down reflux of gastric contents into an already damaged esophagus which cannot muster the peristaltic force necessary to return the gastric contents where they belong The consequence is severe esophagitis often more distressing than the cause of the operation and a major source of blood loss If technically feasible the surgical procedure favored at present is the Heller myotomy which is based on the same principle as forceful dilatation the contractile power of the vestibule is destroyed by placing a longitudinal cut through the muscle but not the mucosa of the narrowed segment Myotomy is however not invariably successful in alleviating dysphagia or preventing reflux esophagitis The lesson is plain once cardiospasm is diagnosed forceful dilatation of the vestibule should be carried out promptly to prevent the progressive enlargement of the esophagus that eventually requires major surgery

DIVERTICULA

Diverticula are found in the esophagus in about 5 per cent of older patients who are given a swallow of barium Most of these pouches occur in the mid and distal esophagus but they are usually small (1 to 4 cm in diameter) and do not cause symptoms Extremely rarely an esophageal diverticulum is subject to ulceration or becomes large enough to cause dysphagia A diverticulum of great clinical importance however is Zenker s diverticulum a pouch which actually arises in the posterior aspect of the hypopharynx but which extends downward between the spine and the esophagus Patients with this condition—elderly males for the most part—suffer dysphagia because swallowed material tends to fill the diverticular sac which then compresses the esophagus Regurgitation of food fouled by stagnation and nocturnal fits of coughing may complicate the picture Diagnosis can usually be made by x ray provided the pharynx is adequately studied as the patient swallows barium Surgical treatment is necessary to relieve the symptoms of a Zenker s diverticulum but may be complicated by mediastinal infection disorders of pharyngeal function during swallowing or recurrence of the diverticulum

OTHER ESOPHAGEAL DISORDERS

Disorders of Motor Function In elderly people normal peristalsis in the lower esophagus above the vestibule may be replaced by so called curling a type of motility which on radiologic study imparts a peculiar beaded appearance to the contracting organ The condition is usually asymptomatic but may be confused radiologically with esophageal varices Rarely the abnormality is sufficiently severe to cause dysphagia The disorder is then known

as *diffuse spasm of the esophagus* or *corkscrew esophagus* because the contracting esophagus appears by x ray to have assumed a bizarre corkscrew pattern

The *lower esophageal ring* is a thin symmetrical annular narrowing located 1 to 4 cm above the diaphragmatic hiatus The ring may be muscular (inferior esophageal sphincter?) or a membranous web but is probably not congenital as it is found more commonly in older patients Five to ten per cent of adults have asymptomatic rings but if the residual lumen is less than 12 mm in diameter the ring may cause a highly characteristic syndrome consisting of intermittent attacks of dysphagia recurring over years unassociated with any other esophageal abnormality and invariably precipitated when the patient swallows meat or other elastic chunks without proper chewing Treatment consists of avoiding such haste

In infants with *chalasia* the normal tonic contraction of the lower sphincter between swallows is absent and free regurgitation from the stomach occurs The condition also affects an occasional adult

About 20 per cent of patients with *scleroderma* suffer esophageal involvement with moderate dilatation of the lumen absent motor function and variable dysphagia In doubtful cases the esophageal changes may be the means of diagnosing scleroderma

Perforation and Rupture Perforation of the esophagus may complicate esophagitis peptic ulcer or neoplasm Rupture may be induced by external trauma or more commonly during instrumentation of the esophagus Sometimes it develops spontaneously in a previously healthy organ The consequences are a syndrome comprising (1) severe pain, usually substernal but occasionally epigastric or precordial and intensified by swallowing (2) free air in the mediastinum producing a mediastinal crunch (Hamman s sign) and subcutaneous emphysema palpable within 1 to 12 hr above the collarbones (3) digestion of mediastinal pleura by pressure and gastric juice with resultant hydro or hemopneumothorax and respiratory embarrassment (4) shock and (5) secondary infection

Spontaneous rupture is a specific entity that develops suddenly during vomiting or coughing, or occasionally merely after injudicious gluttony The tear 1 to 8 cm in length almost invariably is in the posterolateral portion of the esophagus immediately proximal to the diaphragmatic hiatus The diagnosis is to be suspected in elderly males (60 per cent of cases) who are suddenly seized by the typical syndrome while vomiting or coughing it is established by x ray (air in mediastinum or neck, demonstration of laceration by having the patient swallow radiopaque oil pleuropulmonary abnormalities) thoracentesis revealing gastric contents and exclusion of myocardial infarction, pancreatitis and ruptured abdominal viscus Air under the diaphragm is never found in spontaneous esophageal rupture

Perforation or rupture of the esophagus is highly lethal In most cases but particularly those of instrumental or spontaneous rupture of a previously normal esophagus immediate surgical repair of the rent is crucial If surgical repair is not delayed, the mortality of spontaneous rupture can be reduced to 33 per cent

A disorder closely allied to spontaneous esophageal rupture is vertical laceration of the gastroesophageal junction producing, since local vessels are involved severe and usually exsanguinating hemorrhage This so-called *Mallory Weiss syndrome* usually develops when prolonged vomiting follows an alcoholic bout

Foreign Bodies Foreign bodies may cause dysphagia, pain, or perforation of the esophagus Rigid bodies usually are arrested above the aortic arch and elastic material in the distal esophagus Not infrequently a structural abnormality or disease of the esophagus is responsible for stopping the foreign body

Varices Esophageal varices are discussed in Chap 18 p 150 and Chap 250 p 1501 They do not cause dysphagia or other esophageal symptoms Radiologically however their appearance may be confused with that of cancer or esophagitis

Congenital Esophageal Atresias and Fistulas Such atresias often associated with fistulas communicating with the respiratory tract, are found in infants Since these disorders are practically invariably problems of earliest infant life the reader is referred to standard texts on pediatrics for details

Plummer Vinson Syndrome This syndrome is a cause of dysphagia in women with hypochromic anemia Sometimes a pseudoweb is seen in the cricopharyngeal area sometimes mucosal inflammation or atrophy and sometimes no endoscopic or radiologic abnormality whatsoever A good diet and iron are therapeutic

The esophagus is in rare instances affected by the following conditions papilloma, adenoma leiomyoma, cyst leukoplakia, acanthosis nigricans sarcoma and lymphoma

Specific Infections Specific infections which occasionally attack the esophagus are tuberculosis syphilis actinomycosis and thrush.

Extrinsic Disease Diseases of the aorta, heart respiratory tract or mediastinal lymph nodes often displace the esophagus and may appear to narrow the lumen, at least in one diameter Aneurysms of the aortic arch may compress the esophageal lumen against the spine otherwise however dysphagia is rarely produced by extrinsic esophageal masses

and invasion of the esophagus by mediastinal cancer or sarcoma is extremely uncommon

---

For further discussion of problems considered in this chapter the reader is referred to Chap 4 Pain in the Chest and Chap 15 Indigestion Dysphagia Nausea and Vomiting

244 DISEASES OF THE STOMACH

Seymour J Gray

The gastrointestinal tract has often been referred to as the sounding board of the emotions and as such is subject to a host of neurogenic secretory motor hormonal endocrine and vascular influences It must in addition contend with the daily bombardment of exogenous irritants thermal and bacterial variants and mechanical factors

The original observations of Beaumont in 1833 and the later ones of Wolf and Wolff demonstrated the close relationship between emotional disturbances vascular responses increase in gastric secretion and ulcer formation

New vistas appeared through the efforts of Freud Pavlov and Cannon into the mechanisms by which emotional disturbances may reach the stomach The hypothalamus was shown by Cannon to be the seat of primitive emotions probably under *control of centers within the frontal lobe* according to Fulton Emotional and physical duress or injury may stimulate the hypothalamic centers either by neural pathways from the higher centers in the brain or by substances liberated as a result of stress

The neurogenic concept of gastric disease began with Rokitansky in 1842 who postulated a relationship between the stomach and the brain Later Cushing in 1932 demonstrated that stimulation along the course of the fiber tracts from the anterior hypothalamus to the vagal centers produced gastric ulcerations and erosions accompanied by hypersecretion hypermotility and hypertonus

Studies have indicated that chronic emotional and physical duress may also be mediated to the stomach by a pure hormonal pathway through the hypothalamus pituitary and adrenal glands which is independent of the vagus nerve

An understanding of the significance of emotional disturbances is essential to the clinical evaluation of the patient with gastrointestinal complaints The high incidence in the population at large of both gastrointestinal disease and psychologic disorders makes coincidence very common and presents the physician with the challenge to separate the psychologic from the organic components of the history

The physician must be armed with a strong suspicion of malignancy in view of the absence of the classical signs and symptoms" of gastric cancer in 75 per cent of instances until the patient is riddled with metastases The history of early cancer may not differ superficially from that of gastritis or peptic ulcer "Pylorospasm has become a catch all for many types of indigestion" in spite of the fact that pylorospasm per se probably causes no distress unless it is associated with an underlying ulcer gastritis or malignancy

In eliciting the history the physician should investigate recent changes in the character of the distress by outlining a typical day" to determine the hour by hour pain pattern with reference to meals or relief by food or antacids A recent decrease in food intake may signify an early malignancy Inquiry into the family background of gastric cancer or peptic ulcer is helpful but not conclusive A history of tarry stools or hematemesis suggests peptic ulcer gastritis or esophageal varices rather than gastric malignancy Since many organic processes manifest themselves with gastrointestinal complaints inquiry into diseases of the heart and coronary vessels gallbladder kidney and pelvic organs is essential

The nonspecificity of many gastrointestinal complaints emphasizes the importance of integrating a

meticulous history and physical examination with carefully selected laboratory procedures Repeated search for occult blood in the stools by the newer benzidine dihydrochloride method should constitute part of every routine examination The finding of unexplained persistent occult blood by this sensitive test warrants further investigation for malignancy Its use as a screening procedure for cancer is indicated in (1) patients over forty with any gastrointestinal complaints (2) pernicious anemia (3) gastric polyps (4) histamine proved gastric anacidity and (5) gastric ulcer Persistent occult blood in the gastric ulcer patient after 3 to 4 weeks of treatment may indicate malignancy The string test to be described later is helpful in determining the presence and site of upper gastrointestinal bleeding

The histamine test is the most simple reliable and reproducible method of measuring the free hydrochloric acid secretion of the stomach Its principal use is in evaluating *anacidity* rather than degree of hyperacidity Anacidity to histamine stimulation is the best evidence of true anacidity and is important in the diagnosis of (1) pernicious anemia, (2) gastric polyps and (3) gastric cancer Anacidity occurs in 60 to 70 per cent of all gastric cancer patients and in the presence of a *gastric ulcer* is presumptive evidence of cancer since free acid after histamine is almost always present in benign ulcer although it is often *lower* than normal The presence of high acid does *not* exclude cancer Routine gastric analysis is unnecessary in duodenal ulcer since the acid level in any individual patient is not significant diagnostically although the *average* secretion is considerably higher than normal The demonstration of very high values however may be a guide in the treatment

Other newer methods of investigating the gastric contents directly or indirectly include (1) exfoliative cytologic examination for tumor cells obtained with the abrasive balloon or after gastric lavage with chymotrypsin (2) uropepsin excretion in the urine which is a measure of gastric pepsin and (3) urinary test for free gastric acidity with the quininium or azure A exchange indicator compounds

The roentgen examination is indispensable in the diagnosis of gastric disease and is indicated in all patients over forty with epigastric distress The procedure is used most extensively to (1) exclude gastric malignancy (2) establish a diagnosis of peptic ulcer and (3) determine response to treatment, particularly in gastric ulcer if lack of healing suggests malignancy Other indications for roentgenography include (1) persistent occult blood in the stools (2) massive gastric hemorrhage (3) unexplained anemia (4) pernicious anemia (once yearly) and (5) gastric polyps Accuracy of diagnosis approximates 90 per cent

Gastroscopy offers direct visual inspection of the interior of the stomach and is indispensable for the diagnosis of gastritis where roentgen studies are usually nonspecific Additional indications include (1) differential diagnosis of benign and malignant ulcer (2) gastrointestinal bleeding of undetermined origin (3) visualization of small polyps particularly in pernicious anemia (4) evaluation of questionable roentgen findings (5) identification of the type and extent of malignant lesions and (6) identification of foreign bodies The examination is contraindicated in esophageal disease with obstruction extensive esophageal varices severe pulmonary or mediastinal disease aortic aneurysm perforated peptic ulcer peritonitis and marked scoliosis Patients with angina pectoris cardiac decompensation and hypertension tolerate the procedure quite well Gastroscopy should always be preceded by roentgen examination of the chest, esophagus and stomach

Limitations of the procedure are (1) technical problems with incomplete visualization of the lesion (2) difficulties in interpretation and (3) blind areas" which include a small strip of the posterior wall in contact with the instrument a small portion of the lower pole of the stomach the lesser curvature of the antrum and part of the cardia immediately adjacent to the objective

Gastric biopsy obtained with an operative gastroscope or by a flexible vacuum tube inserted into the stomach has contributed further to the diagnosis of gastric disease

GASTRITIS

Gastritis may be defined as an acute or chronic inflammation of the stomach nonspecific in nature involving one or more layers of the gastric mucous membrane

The clinical significance of gastritis stems from its relationship to peptic ulcer pernicious anemia gastric polyps and cancer of the stomach and its tendency to produce ulcerlike symptoms and massive gastric hemorrhage

Acute Gastritis

Irritants and infections are the most common causes of acute gastritis Emotional disturbances may initiate superficial ulcerations which represent the precursors in some instances of chronic peptic ulcer

Etiology and Pathogenesis Acute irritation gastritis is caused by (1) dietary indiscretions (excess coffee tea mustard pepper and curry) (2) alcohol abuse (3) thermal influences (hot food) (4) mechanical distention (voracious eating or a sudden excess of food) (5) chemical irritants (salicylates ammonium chloride quinine digitalis)

(6) corrosive agents (acids lye mercuric chloride) or (7) food allergy in rare instances

Aspirin and alcoholic gastritis deserve special consideration because of the frequency with which they occur Alcohol acts both as an irritant and a powerful stimulant of gastric acidity producing an acute gastritis which may develop later into a chronic atrophic form There appears to be a dif ference in individual susceptibility to alcohol In the gastroscopic examination of 100 men consuming an average of 2 8 pt of alcohol daily for 20 years the stomach was found normal in 55 per cent of the men although severe gastritis was observed in the remaining group despite no apparent difference in nutrition or vitamin intake

Aspirin can produce local inflammation and hemorrhage particularly when introduced into an empty stomach In view of the large amount of aspirin ingested each year the observation of hemorrhage or gastritis following aspirin intake may be coincidental or may depend upon the time interval between food intake and aspirin ingestion

Acute infectious gastritis often accompanies acute bacterial and viral diseases particularly acute in fections of childhood *Acute phlegmonous gastritis* a rare pyogenic inflammation of the gastric wall may follow intraabdominal surgery or result from hematogenous spread of streptococci staphylococci or *Escherichia coli* organisms from septic endo carditis infectious diseases or septicemia

Alarming stimuli and emotional disturbances may produce gastritic ulcerations and an erosive gastritis by altering the circulation of the stomach and in creasing gastric secretion Fatigue and emotional lability appear to lower tissue resistance to irritants infections and other exogenous factors rendering the stomach more susceptible to gastritis particu larly in debilitated or malnourished patients

Pathology The acute inflammatory process is characterized by an interstitial cellular infiltration of the stomach wall with lymphocytes plasma cells and polymorphonuclear leukocytes Edema hemor rhage or erosions of the papillae may be observed depending upon the extent and severity of the in flammation Corrosive agents produce a particularly severe inflammatory reaction with necrosis mu cosal hemorrhage and edema A pangastritis with cystic glandular degeneration and superficial ulcera tion often occurs in the acute infectious type Phlegmonous gastritis is associated with abscess formation and diffuse purulent inflammation with necrosis of the gastric wall

Diagnosis The diagnosis of acute gastritis is made with certainty only by the gastroscopic ex amination which permits direct observation of the stomach lining in its finest details The appearance of the engorged mucosa presenting edema excess mucus erosions and hemorrhages is well described by Beaumont during his observations of Alexis St Martin s stomach seen through a fistula

> There are sometimes found on the internal coat of the stomach eruptions or deep red pimples not numer ous but distributed here and there upon the villus membrane rising above the surface of the mucus coat These are at first sharp pointed and red but frequently become filled with white purulent matter At other times irregular circumscribed red patches varying in size or extent from half an inch to an inch and a half in circumference are found on the internal coat These appear to be the effects of congestion in the minute blood vessels of the stomach

The roentgenographic demonstration of thickened rugae constitutes a presumptive diagnosis of gas tritis Superficial ulcerations do not invade the muscularis and therefore cannot be visualized al though they may produce bleeding and pain

Symptoms Acute gastritis is often a self limited disease producing no symptoms In some instances depending upon the intensity and duration of the provocative agent and the individual s susceptibility the patient may complain of epigastric burning fullness anorexia nausea or vomiting A gnawing ulcerlike pain and gastric hemorrhage are common with erosive gastritis particularly after acute alcohol excess prolonged aspirin intake or ingestion of corrosive substances

Morning nausea and vomiting is a prevalent symptom among patients with alcoholic gastritis usually appearing after the first swallow of food or liquid upon arising Aspirin may produce epigastric pain or bleeding in patients with duodenal or gastric ulcer with or without an associated gastritis Perfor ation shock or pyloric obstruction resulting from scar tissue formation are complications of acute cor rosive gastritis Acute phlegmonous gastritis is char acterized by the sudden onset of acute abdominal pain and high fever associated with chills vomit ing and prostration simulating the perforation of peptic ulcer acute cholecystitis or pancreat tis

Treatment Since the disease is usually self limited no specific therapy is indicated other than the removal of irritants or other provocative agents avoidance of dietary indiscretions and the treat ment and prevention of infection An ulcerlike regimen with antacid therapy may be helpful in erosive gastritis In acute corrosive gastritis the proper antidote should be administered as soon as the corrosive agent is removed and further intuba tion avoided because of the danger of perforation and hemorrhage The treatment of acute phleg matous gastritis consists of intensive antibiotic therapy surgical drainage of the localized abscess and in rare instances subtotal gastrectomy The

management of hemorrhage will be discussed in Chap 245

Chronic Gastritis

Chronic gastritis may result from any form of acute gastritis and is caused by (1) chronic irritation (2) dietary indiscretions (3) chronic infections (4) stress and emotional disturbances (5) chronic circulatory disturbances (chronic congestion) (6) deficiency states and (7) prolonged roentgen radiation Other etiologic factors remain to be determined

Roentgenography may suggest the presence of chronic gastritis but the specific diagnosis depends upon the gastroscopic or histologic examination A correlation between the histologic and gastroscopic diagnosis has been documented by Schindler although recent gastric biopsy studies do not establish this relationship consistently Three types of chronic gastritis have been described chronic superficial, atrophic and hypertrophic gastritis

Chronic Superficial Gastritis

This disease comprises approximately 25 per cent of all chronic gastritis and is characterized gastroscopically by (1) hyperemia and reddening of the mucous membrane (2) edema (3) patches of adherent sticky white or whitish gray mucus and (4) mucosal hemorrhages and small erosions

Pathology The histologic abnormalities occur in *the mucosa and submucosa where edema plasma* cells and red cells are observed beneath the surface epithelium Interruptions in the continuity of the mucosa over hemorrhagic areas represent hemorrhagic erosions

Chronic Atrophic Gastritis

This chronic inflammatory disease which constitutes 35 per cent of all chronic gastritis leads to the progressive destruction of the gastric glands

The gastroscopic picture presents (1) a gray or greenish gray color caused by the thinning of the mucosa, as contrasted to the orange red color of the normal stomach and (2) branching blue or purple blood vessels visible through the thin mucosa

Pathology The pathologic picture is characterized by (1) marked thinning of the mucosa, (2) disappearance of the chief and parietal cells of the gastric glands (3) transformation of epithelial cells into goblet cells (4) extensive interstitial infiltration with plasma cells and (5) metaplasia to an intestinal type of epithelium Uncomplicated atrophic gastritis is unaltered histologically by its association with gastric malignancy or pernicious anemia.

Relationship to Pernicious Anemia Polyps and Cancer An atrophic mucous membrane is invariably present at autopsy in pernicious anemia and occurs in a high percentage of patients with gastric polyps and gastric cancer There is considerable evidence that the atrophic mucosa is the precursor of these diseases Adenomatous polyps were found in 7 to 14 per cent of a series of 878 collected cases of pernicious anemia studied by roentgenography gastroscopy or autopsy (Table 123) Carcinoma of the stomach occurred in 4 to 12 per cent of this series and was observed three to eight times more frequently than in a control group of the same age

Chronic Hypertrophic Gastritis

This form of gastritis is characterized by hyperplasia and thickening of the gastric mucosa a tendency towards tumefaction hemorrhage and ulcer like symptoms It comprises 40 per cent of all chronic gastritis

Table 123 INCIDENCE OF ATROPHIC GASTRITIS ADENOMATOUS POLYPS AND CARCINOMA OF THE STOMACH IN PERNICIOUS ANEMIA

Investigators	Total cases of pernicious anemia examined	Polyps	Carcinoma	Atrophic gastritis	Method of study
Brown	151	12 (8%)		151 (100%)	Autopsy
Hardt Schwartz Steigmann	100	7 (7%)	4 (4%)	59 (59%)	Gastroscopy
Kaplan and Rigler	293		36 (12 3%)		Autopsy
Rigler and Kaplan	211	15 (7 1%)	17 (8 0%)		X ray
Schindler	43	6 (14%)		43 (100%)	Gastroscopy
Young Loefenstein Cray	80	8 (10%)	4 (5 0%)	[illegible]	Gastroscopy

The gastroscopic appearance is that of a velvety cobblestone mucosa with diffuse granular nodularity Sometimes these polypoid excrescences may be difficult to distinguish from true polyps or tumor infiltration Erosions or small ulcerations are common

Pathology Hypertrophic gastritis may occur as (1) hypertrophic interstitial gastritis with dense lymphocytic and plasma cell infiltration and (2) hypertrophic proliferative gastritis in which there is a marked proliferation of the surface epithelium forming irregular nodes A tremendous overgrowth of the glandular apparatus may treble the thickness of the mucosa in some instances simulating a neoplasm

Postoperative Gastritis

Severe hypertrophic or erosive gastritis may occur following gastric resection or gastroenterostomy for peptic ulcer The gastritis is often localized to the site of the anastomosis or may involve the entire stomach Postoperative gastric distress or hemorrhage may result The treatment is the same as that of recurrent ulcer

Symptoms of Chronic Gastritis Chronic gastritis is often asymptomatic Ulcerlike distress may occur with superficial and hypertrophic gastritis particularly if erosions are present The pain differs usually from that of true peptic ulcer in its time relationship and persistence after food Anorexia and epigastric burning are not uncommon Gastric acidity is usually increased in hypertrophic gastritis and is absent in one third of the patients with atrophic gastritis

Massive hemorrhage is a frequent complication of hypertrophic gastritis and is seen in atrophic gastritis when a submucosal vessel is eroded Gastritis bleeding plays a significant role in massive hemorrhage of undetermined origin since the source may not be identified roentgenographically

Course and Prognosis Chronic superficial gastritis is usually self limited and heals rapidly Occasionally it develops into atrophic gastritis The atrophic form remains unchanged in spite of liver or vitamin therapy and deserves repeated examination because of the increased incidence of gastric cancer Hypertrophic gastritis has little tendency to heal and usually persists in spite of treatment

Treatment There is no specific treatment An ulcer regimen including a bland diet and antacids may relieve the distress when ulcerations are present Liver extract and vitamins have been reported to reverse the gastroscopic appearance of atrophic gastritis but there is no evidence that the histologic or clinical picture is improved

GASTRIC ULCER

Benign gastric ulcer will be discussed in Chap 245

TUMORS OF THE STOMACH

Benign Tumors of the Stomach

Definition Benign gastric tumors may be of epithelial or connective tissue origin The epithelial tumors consist of adenomatous polyps adenomas and papillomas The connective tissue tumors include (1) smooth muscle tumors (leiomyomas fibromyomas myomas and adenomyomas) (2) neurogenic tumors (neurilemmomas and neurofibromas) (3) lipoma (4) angioma (hemangiomas and lymphangiomas) (5) dermoid cysts and (6) myxomas osteomas chondromas and lymphomas A rare benign tumor of the stomach is caused by proliferation of aberrant pancreatic tissue

Gastric Polyps

Pathology Adenomatous polyps the most common of all epithelial tumors appear most frequently in the pyloric region of the stomach The benign gastric polyp is usually an adenoma although the term *polyp* refers to its gross rather than its histologic structure Adenomas are composed of epithelial tubules with a connective tissue stroma which rarely breaks through the muscularis mucosa and they appear as sessile or pedunculated tumors loosely attached to the mucous membrane by a pedicle of varying length Solitary adenomas occur in one half the cases

Menetrier introduced the term *polyadenomes polypeux* in 1888 to describe multiple adenomas of the stomach (*diffuse polyposis*) consisting of innumerable discrete lobulated pedunculated often cystic tumors each with its own independent attachment to the stomach mucosa The disease usually is seen in the antrum although the whole stomach may be involved In rare instances polyposis of the colon occurs concomitantly (Fig 171)

The most important aspect of the adenomatous polyp particularly of the large polyp associated with anacidity is its tendency to malignant change The relationship of polyp formation to gastric anacidity atrophic gastritis pernicious anemia and carcinoma is discussed elsewhere (Table 123)

Another form of polyposis called *polyadénomes en nappe* presents a thickened plaquelike base characterized by closely packed flat projections from the mucous membrane without pedicles or cystic changes They are not true adenomas but represent simple hypertrophy or hyperplasia of the gastric mucosa grafted upon a severe hypertrophic gastritis These lesions do not undergo malignant

change and are often described as *giant hypertrophy of the gastric rugae* or *giant hypertrophic gastritis*

Connective Tissue Tumors

Smooth muscle tumors occur most commonly near the pylorus as either solitary or multiple neoplasms They usually project into the stomach lumen as pedunculated intragastric tumors but may involve the subserous coat growing within the confines of the gastric wall or extending outside the stomach Neurogenic tumors are most commonly found on the lesser curvature near the pylorus and angiomas usually occur in the body and antrum of the stomach

Symptoms of Benign Tumors Benign tumors of the stomach produce no symptoms unless they obstruct the pylorus ulcerate or bleed A polyp may prolapse through the pylorus and occasionally cause obstruction The most consistent symptom is anemia resulting from continuous bleeding This may take the form of massive hemorrhage or continuous oozing Usually the anemia is of the hypochromic iron deficiency type but macrocytic anemia may occur with gastric polyps Large mesenchymal tumors may present an abdominal mass or they may ulcerate producing postprandial discomfort suggestive of peptic ulcer

Diagnosis Adenomatous polyps are diagnosed by gastroscopic examination or the roentgen demonstration of a round discrete movable filling defect in a pliable stomach wall Histamine anacidity is commonly associated

Mesenchymal tumors occur at any age but the diagnosis is suggested by its appearance in the younger age group Demonstration of a circumscribed intramural mass suggests a connective tissue tumor Gastroscopically the tumor appears to lie beneath an intact mucosa and moves with the wall of the stomach during peristaltic activity When a benign tumor ulcerates differentiation from a malignant lesion becomes more difficult

Treatment All benign neoplasms of the stomach should be removed surgically The possibility of malignant change exceeds the operative mortality risk Operation is often required because of hematemesis melena severe anemia or symptoms of obstruction at the pylorus or antrum Subtotal gastric resection is the operation of choice although in some instances *a small polyp may be excised* locally Simple excision however has been followed in a number of instances by the occurrence of a malignant lesion at the site of the original growth Total gastrectomy may be necessary in cases of diffuse polyposis and multiple benign tumors Prognosis following adequate removal of the benign gastric neoplasm is excellent.

FIG 171 Multiple polyps of the stomach The classical picture of *polyadenomes polypeux* in a 53-year-old woman with a history of hematemesis Total gastrectomy was performed, and the stomach revealed 35 to 40 benign polyps each with a discrete stalk.

Carcinoma of the Stomach

Cancer of the stomach ranks high among the common causes of death It is responsible for approximately 25 000 deaths in the United States annually and 10 per cent of all cancer deaths Although it may occur in patients under twenty years of age and is not uncommon from thirty five to fifty the incidence increases with maturity and is highest between the ages of fifty and sixty nine with a male preponderance The disease is encountered among all races in all parts of the world.

Etiology The cause of gastric cancer is unknown *There is no conclusive proof that alcohol hot foods* or superheated fats are carcinogenic in human beings The incidence of gastric cancer is unrelated to trauma, occupation or dietary indiscretion. Although susceptibility to gastric cancer appears to be inherited in some families it is doubtful that heredity is a primary factor Filtrable viruses and various carcinogens such as methylcholanthrene are

under investigation The concept of benign gastric ulcer as a precancerous lesion which has not been universally accepted will be discussed in Chap 245

Significance of Atrophic Gastritis in Gastric Cancer The relationship of gastric polyps and cancer to an atrophic gastric mucous membrane has been referred to in the discussion of atrophic gastritis (Table 123) The demonstration of the transitional stages from chronic atrophic gastritis with small areas of regenerative hyperplasia to papilloma and finally to carcinoma led Konjetzny and other investigators to consider the atrophic mucosa as a precancerous lesion offering fertile soil for the growth of gastric cancer

In the authors series of 80 pernicious anemia patients four cancers (5 per cent) and eight polyps (10 per cent) were observed all occurring in the antrum of stomachs with atrophic gastritis (Table 123) It does not follow that every atrophic membrane will undergo malignant change or that all cancers arise on the basis of a chronic atrophy Although gastric cancer may appear in an essentially normal gastric mucosa the probability of developing cancer is three times greater in patients with chronic atrophy than in the average normal adult in the same age group

Pathology Approximately 50 per cent of all gastric cancers occur in the antrum or pyloric canal and 25 per cent involve the lesser curvature The cardia and greater curvature are each involved in approximately 8 per cent the remaining 9 per cent of tumors occurring on the anterior and posterior walls of the body of the stomach Cancers of the cardia or pylorus often produce symptoms before the tumor achieves any great size but lymphatic invasion to the regional nodes occurs comparatively early Cancer involving the pyloric canal or adjacent antrum may be the most malignant metastasizing early before the growth has achieved any remarkable size In general however the site of the growth does not significantly alter the prognosis although it may influence early diagnosis Large primary tumors often metastasize less rapidly than small neoplasms

Grossly the tumor appears as (1) a polypoid mushroomlike sharply circumscribed growth protruding into the lumen of the stomach (2) an ulcerating cancer or (3) a diffusely infiltrating lesion

Cancer of the stomach may exist as a simple adenocarcinoma or as a papillary colloid gelatinous medullary or scirrhous carcinoma The *circumscribed* scirrhous carcinoma often produces the common type of ulcerating cancer which may simulate benign gastric ulcer Histologically the tumor presents an excess of fibrous tissue with cancer cells appearing between the strands of connecting tissue Early invasion of the regional lymph nodes is common The *diffuse* scirrhous carcinoma transforms the stomach into a rigid shrunken thick walled inflexible structure—the so called leather bottle stomach or *linitis plastica*

The malignancy of tumors may be classified on the basis of degree of differentiation microscopically (Broders classification) The well differentiated tumors metastasize least rapidly and present the best prognosis whereas the poorly differentiated tumors tend to metastasize early

Gastric cancer spreads by direct extension or infiltration to the pancreas liver colon gallbladder esophagus spleen or diaphragm and least often to the duodenum Metastasis takes place by way of the lymphatics peritoneum or blood stream The regional lymph nodes are the first to be involved The next most common sites are the omentum peritoneum and liver followed by the left supraclavicular lymph nodes rectum ovaries lungs bones adrenal glands and brain approximately in that order Metastases to the navel skin and bone marrow are rare

The left supraclavicular node (Ewalds node Virchows node sentinel node) is involved in approximately 5 per cent of cases of gastric cancer at autopsy This involvement appears late in the disease The so called *Krukenberg tumor* may occur in an equal number of cases as a result of peritoneal spread invariably involving both ovaries Metastases in the rectal pouch of the male may present themselves as the *rectal shelf of Blumer*

Symptoms The onset of carcinoma of the stomach is so insidious that an estimated 50 per cent of all gastric cancers extend beyond the stomach before the first symptoms appear and 12 to 18 months usually elapse before the diagnosis is made Symptoms are frequently completely absent or very indefinite in nature until the growth has attained sufficient size to produce ulceration bleeding obstruction or secondary infection Alertness on the part of the physician to the early diagnosis of gastric cancer offers the only hope at present to more successful therapy

Anorexia vague epigastric discomfort slight nausea after meals and weight loss of 10 to 15 lb are among the first signs of gastric cancer Nausea and vomiting associated with fullness after meals may indicate beginning pyloric obstruction or interference with gastric motility and distensibility Intractable vomiting of food and gastric juice may be an early symptom of small tumors invading the pyloric canal although it usually occurs late in the disease The vomitus contains food bile or blood presenting a "coffee grounds" appearance resulting from the prolonged action of hydrochloric acid

Epigastric distress if present is exceedingly variable It may consist of vague discomfort in the epi

gastrium a sensation of fullness burning or a very mild cramping distress occurring after a heavy meal or minor dietary indiscretion A true ulcerlike syndrome may be the principal complaint particularly if the ulceration is associated with acid gastric juice or if the lesion is located in the distal portion of the stomach interfering with normal tone and motility In some instances it cannot be distinguished from true ulcer distress but usually the *relief of pain after foods or antacids is incomplete* and the pain occurs shortly after meals and before breakfast

Hematemesis and melena may be the presenting symptoms or may not occur until late in the disease *Anemia is often but not invariably present*

Occasionally perforation of an ulcerating cancer or a septic fever (suggesting abscess or metastases to the liver) may be the first clinical manifestation Low grade fever is not uncommon with gastric cancer Carcinoma of the cardiac portion of the stomach simulates diseases of the lower esophagus and may produce vague substernal distress or slight dysphagia *following solid food intake*

Physical Examination In the early stages there are no discernible abnormalities As the disease progresses weight loss pallor a palpable movable hard mass in the upper abdomen or nodular enlargement of the liver may become evident A firm hard node in the left supraclavicular area (Ewald s node Virchow s node or sentinel node) is a late and infrequent finding Metastases to both ovaries (Krukenberg s tumor) are likewise uncommon Metastatic involvement of the prerectal cul-de sac presents a hard shelflike projection or mass above the prostate or in a similar position in the female (*rectal or Blumer s shelf*) Normal soft velvety rectal mucosa can be palpated overlying the neoplasm distinguishing it from an intrarectal growth

Laboratory Examination There is no free hydrochloric acid in the gastric juice after histamine stimulation in approximately 60 to 70 per cent of patients with gastric cancer In the presence of an ulcerating gastric lesion persistent anacidity is highly suggestive of malignancy since free acid is usually demonstrable with a benign gastric ulcer Normal or increased gastric acidity however does not exclude the diagnosis of cancer Occult blood in the gastric contents or the stools is found in a large percentage of cases at some time during the course of the disease The stools may be consistently negative however in the presence of an *extensive cancer of the stomach The blood count* is often normal or discloses a normocytic or hypochromic microcytic anemia particularly if there is chronic blood loss Direct suppression of the bone marrow can produce definite anemia in the absence of blood loss Characteristic malignant cell nuclei may be found upon staining the gastric sediment by Papanicolaou s method particularly with a more cellular type of lesion or following the use of an abrasive balloon or gastric lavage with papain or chymotrypsin

Plasma and Urinary Pepsinogen in Gastric Cancer The plasma and urinary pepsinogen (uropepsin) *reflect the peptic activity of the stomach* Plasma pepsinogen is derived from the secretion of pepsinogen directly into the blood stream by the peptic cells Pepsinogen is then transported to the kidneys and excreted in the urine as uropepsin The uropepsin excretion usually exceeds 1 000 units in normal individuals and in patients with duodenal or benign gastric ulcers In the presence of a gastric lesion a very low uropepsin excretion suggests malignancy (Table 124) although a normal excretion does not exclude it A low plasma pepsinogen in the presence of gastric ulceration is also a strong indication of cancer

Roentgenologic Examination *The roentgenologic* examination is the most reliable method for detecting gastric cancer Careful fluoroscopic study and repeated examinations yield an accurate diagnosis in approximately 90 per cent of cases

The most common roentgen evidence of gastric cancer is the "filling defect which appears as a

Table 124 UROPEPSIN EXCRETION IN PEPTIC ULCER GASTRIC CANCER AND PERNICIOUS ANEMIA

Condition	Patients	Average uropepsin excretion units/24 hr	Uropepsin excretion units/24 hr percentage		
			0–1 000	1 000–3 000	3 000+

Gastric ulcer	90	5 756	1 1	19 3	79 6
Gastric cancer	73	1 939	57 5	19 2	23 3
Pernicious anemia (atrophic gastritis)	80	13	100	0	0

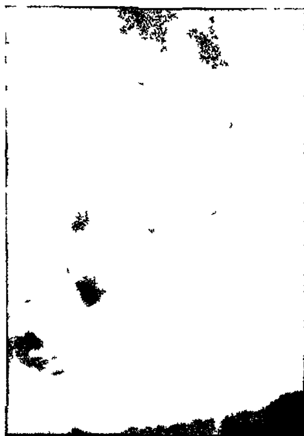

Fig 172 Ulcerating colloid adenocarcinoma of the lesser curvature The crater is surrounded by an irregular halo produced by the thickened infiltrated wall surrounding the ulcer The patient presented profound anemia and metastases to the lymph nodes and bone marrow

constant often rigid space occupying lesion subtracting from the normal outline of the stomach A polypoid tumor growing into the lumen appears as an opaque often nodular mass when pressure is exerted over the barium filled area

An ulcer appears as a collection of barium in a crater or niche It is considered malignant when associated with a space occupying deformity or filling defect Ulcers on the greater curvature of the stomach have a high incidence of malignancy An ulcer with a thickened raised wall appears as a crater (or a collection of barium) surrounded by a translucent halo the meniscus sign of Carman which suggests malignancy particularly if observed beneath the line of the lesser curvature (Fig 172)

The scirrhous type of cancer produces a constant rigid often ragged alteration in the contour of the stomach with destruction or distortion of the mucosal pattern (Fig 173) Both curvatures of the antrum may be involved producing a stiff annular defect surrounding a narrowed lumen (Fig 174) The diffuse scirrhous carcinoma may give rise to a typical small contracted stomach referred to as the leather bottle stomach described previously

Approximately one fifth of all gastric cancers present clinical and roentgen evidence of obstruction When there is complete obstruction it may be impossible for the roentgenologist to distinguish a pyloric cancer from a duodenal ulcer with high grade stenosis Obstruction from cancer is more likely to be complete and the contour of the obstructed area is often more ragged as a result of infiltration

Malignant lesions of the cardia of the stomach which have not invaded the lower esophagus or the lesser curvature may be overlooked by roentgen examination Examination by esophagoscopy gastroscopy and the double contrast technique with air and barium are helpful in the detection of lesions in this area

Gastroscopic Examination Gastroscopic examination of the stomach complements the roentgen examination and should always be preceded by it The maximum diagnostic accuracy is obtained by employing both methods since either alone may fail to demonstrate a lesion If the roentgenographic findings are conclusive however gastroscopy is *not essential* The procedure is *often helpful in* evaluating questionable roentgen defects or con

Fig 173 Undifferentiated adenocarcinoma of the lesser curvature of the stomach in a 29 year old man with metastases to the liver and supraclavicular nodes

firming the diagnosis of cancer and determining the type extent and operability of the tumor Gastroscopy may be employed to help differentiate benign from malignant lesions and intragastric from extragastric tumors Cancers on the posterior wall of the fundus or at the cardia which are often difficult to visualize roentgenologically may be seen gastroscopically in some instances

Polypoid malignancies are readily recognized since they protrude into the lumen although the differentiation from benign tumors or hyperplastic forms of gastritis is difficult.

A negative gastroscopic examination does not exclude the diagnosis of cancer associated with lesions in the "blind areas" of the stomach

The interpretation of the gastroscopic picture is dependent largely upon the skill and experience of the endoscopist Infiltrating carcinomas are difficult to distinguish gastroscopically from lymphoma and diffuse hypertrophic gastritis Gastric biopsy in these instances may be helpful

An ulcerating carcinoma is characterized by (1) nodularity or stiffness of the wall (2) blending of the borders of the ulcer which lack the cleanly cut sharply punched-out appearance of the benign lesion and (3) stiffness nodularity or infiltration throughout the area

Early Diagnosis and Screening Procedures Approximately 75 per cent of all patients with gastric cancer who come to operation cannot be cured because of lymph node metastases Since the symptoms of early cancer of the stomach are absent vague or indefinite necessitating a period of 12 to 18 months for recognition early diagnosis and treatment are of prime importance

Earlier diagnosis may be achieved by (1) repeated roentgenographic and gastroscopic examinations in all patients in middle life who develop indigestion or abdominal distress (2) viewing all gastric ulcers with suspicion until they are healed completely according to roentgenographic and gastroscopic examination (3) removing gastric polyps as soon as they are found particularly if there is an associated histamine anacidity and (4) subjecting patients with pernicious anemia and chronic atrophy of the stomach to repeated roentgen and gastroscopic examinations at regular intervals

Further advances in early diagnosis may be forthcoming from cancer prevention clinics and screening procedures such as routine photofluorography of the stomach and the newer techniques of exfoliative cytology for the early demonstration of cancer cells Increased accuracy of cytologic diagnosis has been made possible by gastric lavage with papain or with chymotrypsin and the use of abrasive balloons The technical complexities of this cytologic technique prevent its wide use as a screening procedure although selected screening is feasible

Fig 174 Annular adenocarcinoma of the stomach involving the antrum producing a narrowed lumen in a 60 year-old male with a 10-year history of pernicious anemia

particularly in differentiating benign from malignant gastric ulcer The use of gastroscopic biopsy may also help in correlating tissue morphology with the cell type seen in the cytologic preparation

Other screening procedures include (1) examination of the stools for occult blood by the benzidine dihydrochloride method (2) the determination of free gastric hydrochloric acid by a urinary method using the quininium or azure A exchange indicator compounds and (3) the measurement of the uropepsin excretion in the urine discussed previously

Differential Diagnosis An ulcerating cancer of the stomach may simulate a benign gastric ulcer particularly in the early phase of the disease The methods of distinguishing benign from malignant ulcers of the stomach by clinical laboratory roentgenologic and gastroscopic criteria are discussed in Chap 245

Complications The complications of gastric cancer are (1) perforation into adjacent organs (2) hemorrhage (3) obstruction (4) metastatic involvement to other parts of the body Acute perforation is rare Chronic perforation into the pancreas and less frequently into the duodenum jejunum or colon occurs late in the disease and may be recognized clinically by the onset of severe pain or the presence of a palpable mass produced by the inflammatory reaction

While oozing and minor bleeding from gastric carcinoma are common as evidenced by the presence of occult blood in the stools or the coffee grounds appearance of the vomitus massive hemorrhage occurs less frequently in cancer than in benign peptic ulcer

Obstruction from lesions invading the pylorus or cardiac orifice of the stomach may cause pain nausea and vomiting or dysphagia Constricting *lesions in the middle of the stomach* producing the so called *hourglass stomach* rarely cause obstruction

Prognosis and Mortality Rate Lymph node metastases are demonstrable in 65 to 75 per cent of patients who come to operation In this group the 5 year survival rate when gastric resection is possible is only 5 to 10 per cent Of the remaining 25 to 35 per cent of patients who are operated on for gastric cancer with no demonstrable lymph node involvement the survival rate is approximately 35 per cent The survival rate for all patients with gastric cancer probably does not exceed 12 per cent although statistics for the country as a whole would indicate that 5 to 8 per cent of all persons coming to a clinic or hospital with gastric cancer survive 5 years or more This figure includes patients who are frankly inoperable as well as those who are submitted to palliative operative procedures The prognosis is not affected significantly by sex or age although carcinoma may spread more rapidly in the young

The immediate surgical mortality rate depends upon the individual s surgeon s criteria for resectability A high mortality rate above 10 per cent may indicate that too many resections are being attempted while the mortality rate of 5 per cent or less may indicate too few Recent mortality rates approximate 8 per cent for subtotal resection and 13 per cent for total resection for gastric cancer The only hope for this disease at the present time is early diagnosis and a reasonably heroic surgical approach

Treatment All ulcerating lesions of the stomach should be viewed with considerable suspicion until they prove to be benign When a gastric ulcer appears benign by roentgen and gastroscopic examination a trial of medical ulcer management with antacids and antispasmodics is justified for a period of 4 to 8 weeks if free gastric acidity can be demonstrated and the cytologic examination of the gastric contents is negative If the lesion does not heal completely by roentgen and gastroscopic examination after 4 to 8 weeks of good medical management or if abdominal pain or occult blood in the stools persists and there is reasonable doubt of the diagnosis of benignity then surgical exploration is indicated (The differential diagnosis and treatment of gastric ulcer is discussed in Chap 245)

The ideal treatment for the early lesion of gastric cancer is complete surgical removal by subtotal gastric resection The more advanced gastric cancer regardless of the gross or histologic appearance also should be removed if possible by subtotal or total gastric resection Total gastrectomy for lesions diffusely infiltrating the stomach wall with *excision of the entire lymphatic drainage area* is now being recommended since life may be prolonged by the procedure in spite of the lymphatic involvement The simultaneous removal of a gastric cancer and metastatic lesions elsewhere such as ovarian implantations may prove beneficial Although metastases to the peritoneum bone marrow and liver are considered relative contraindications to resection a subtotal palliative resection in selected cases is often indicated particularly when the tumor threatens obstruction If the tumor cannot be resected a gastroenterostomy is unlikely to be helpful

Medical management consists of symptomatic supportive and psychologic treatment of the patient A soft bland high caloric palatable diet as unrestricted as possible is prescribed as tolerated The diet is supplemented with iron and vitamins Narcotics may be used freely but discriminately along with sedatives hypnotics and analgesics The parenteral administration of fluid and electrolytes and occasional blood transfusions are helpful as supportive measures A bland ulcer type of diet with frequent feedings antacids and antispasmodics may afford symptomatic relief to patients with ulcerating cancers particularly those with free acid in the gastric juice

There is no satisfactory proof that roentgen therapy is of value in the treatment of gastric cancer although it is effective in the treatment of lymphoblastoma and malignant mesenchymal tumors of the stomach The nausea vomiting and anorexia induced by intensive radiation therapy contraindicate its use in gastric carcinoma The therapeutic value of high voltage deeply filtered therapy which may be applied directly to the tumor without injury to other tissues remains to be determined

Psychologic Approach to the Patient As a general principle it is advisable to withhold the diagnosis of gastric cancer from the patient but it should be freely and openly discussed with the next of kin or a responsible member of the family particularly from the viewpoint of diagnosis and treatment Most patients eventually know they have cancer but cling to the ray of hope that they may be mistaken This reasonable doubt regarding the diagnosis exerts a sustaining influence in their atti

tude to the disease The patient may repeatedly interrogate the physician and urge him outwardly to reveal the diagnosis hoping fervently that the true facts will not be divulged Cautious optimism on the part of the physician is necessary in the day to-day handling of the problems which arise

Above all the physician must encourage and sustain the patient with a positive hopeful optimistic approach New drugs and treatments offer new hope In selected instances oral cortisone in doses of 100 to 150 mg daily may be exceedingly (although temporarily) helpful in increasing the patient s appetite producing a state of euphoria and sustaining the patient psychologically during the terminal period It does not of course alter the course of the disease If used judiciously in the absence of electrolyte imbalance or marked vomiting cortisone may be a blessing to the patient and the family during the last trying days

Malignant Tumors of the Stomach Other Than Carcinoma

Definition This group of tumors includes sarcoma lymphosarcoma reticulum cell sarcoma Hodgkin s disease and lymphoblastoma Sarcomas constitute 1 to 4 per cent of all tumors of the stomach Among the sarcomas the reticulum cell sarcoma (31 per cent) and leiomyosarcoma (27 per cent) are the most common Lymphosarcoma (23 per cent) Hodgkin s disease (15 per cent) and lymphoblastoma (4 per cent) complete the list

Symptoms The age of onset of sarcoma is approximately 10 years younger than that of carcinoma The most prominent symptoms are pain loss of weight and a palpable mass Splenomegaly occurs in 10 per cent of gastric sarcoma Massive bleeding is a common complication particularly with leiomyosarcoma Obstruction and perforation are rare

Sarcomas may invade the blood stream more often than carcinoma although lymphatic permeation and metastases are seen more often with carcinoma The neurogenic sarcoma lymphosarcoma and fibrosarcoma metastasize late in the course of the disease although the round cell tumors and the myosarcomas are much more malignant growing rapidly and metastasizing early

Enlargement of the superficial glands occurs with lymphosarcoma and Hodgkin s disease Anemia splenomegaly fever an abdominal mass and lymphadenopathy suggest the diagnosis of Hodgkin s disease

Diagnosis The roentgen appearance of sarcoma may simulate that of carcinoma The differential between the two is difficult and often depends upon the histologic examination In some instances gastric biopsy has been helpful and exfoliative cytology may be useful Biopsy of large glands from the cervical region is often indicated Gastroscopically the differential between carcinoma sarcoma and leukemia or Hodgkin s disease is exceedingly difficult

Treatment These tumors in general are considerably more radiosensitive than carcinoma Gastric resection followed by roentgen therapy is advocated Lymphosarcoma is more responsive to deep radiation therapy than any other type of gastric tumor particularly the small round cell lymphosarcoma Good results from roentgen therapy have also been reported in Hodgkin s disease of the stomach

DISEASES SIMULATING GASTRIC MALIGNANCY

A number of disease processes are characterized by diffuse inflammatory reaction and ulceration which resemble malignant infiltration and present difficulties in clinical and roentgen diagnosis

Giant Rugal Hypertrophy Occasionally giant enlargement of the mucosal folds presents the appearance of neoplasm both roentgenologically and gastroscopically A combination of hypertrophy and hyperplasia may appear as *polyadenomes en nappe* sometimes called *giant hypertrophy of the gastric rugae* or *giant hypertrophic gastritis* Gastric biopsy and exfoliate cytology may be helpful in diagnosis but gastric resection is often necessary because of the difficulty in distinguishing this disease from cancer or lymphoma (Fig 175)

Linitis Plastica *Linitis plastica* is a term selected by Lewis Brinton in 1854 to describe an excessive connective tissue response to malignancy or infection of the stomach This disease is characterized by a diffuse fibrosis of the gastric wall associated with shrinkage thickening and a diminished capacity It is sometimes called *leather bottle stomach* or *cirrhosis of the stomach* The principal pathologic finding is extensive connective tissue proliferation in the submucosa The disease is most common in males between the ages of forty and seventy

Etiology The principal causes are (1) diffuse scirrhous carcinoma or occasionally gastric sarcoma Hodgkin s disease or leukemia (2) gastric syphilis (3) phlegmonous gastritis

Symptoms The initial complaint is that of a feeling of fullness after a small meal accompanied by regurgitation and vomiting A progressive decrease in gastric capacity results in marked weight loss and anemia Hematemesis perforation and obstruction are rare

Diagnosis Roentgenograms present a smooth rigid contracted stomach with diminished peristalsis

FIG 175 Giant rugal hypertrophy presenting the appearance of a neoplasm in a 47 year old man with melena Microscopic examination revealed a thickened mucosa with elongated cystically dilated gastric glands There was no evidence of malignancy

and rapid evacuation of the barium The gastroscopic appearance is that of diffuse infiltration and stiffness of the mucosa A mass may be palpated in some instances Achlorhydria occurs in approximately 75 per cent of cases

Treatment Linitis plastica must be regarded as a malignant lesion unless proved otherwise The surgical treatment is that of gastrectomy frequently *total gastrectomy If the Wassermann test is positive* surgery should be deferred until the patient has been given antisyphilitic therapy

Syphilis of the Stomach The characteristic lesion of this rare disease is the gumma It may appear as a solitary lesion with ulceration simulating a benign gastric ulcer or as a chronic inflammatory reaction with fibrosis and nodular induration simulating a carcinoma The histologic picture is characterized by perivascular round cell infiltration gummas and obliterating endarteritis

Epigastric ulcerlike pain vomiting gastric hemorrhage and weight loss may occur A mass is rarely palpable Differentiation from cancer may be impossible without a histologic examination The roentgen examination may demonstrate (1) an infiltrative lesion in the prepyloric area (2) constriction of the middle of the stomach resulting in an hour glass deformity (3) diffuse involvement presenting the picture of a linitis plastica The Wassermann test on blood or spinal fluid is frequently positive

Syphilitic lesions of the stomach respond dramatically to antisyphilitic therapy

Tuberculosis of the Stomach Tuberculosis of the stomach is a rare disease encountered more frequently in adults than in children Three types are usually seen ulcerative miliary and granulomatous The ulcerating type is the most common form Clinically it may be impossible to differentiate tuberculosis of the stomach from benign ulcer syphilis or cancer In the vast majority of patients tuberculosis exists elsewhere in the body particularly in the lungs The diagnosis is established by microscopic examination of the lesion removed at laparotomy or by the demonstration of tubercle bacilli

Congenital Hypertrophic Stenosis in Adults The adult form similar to the disease seen in infants consists of a marked hypertrophy and thickening of the pyloric circular muscle

Etiology The cause of this syndrome is unknown In some instances it represents a residual low grade congenital pyloric stenosis producing periodic episodes of nausea and vomiting which can be traced back to infancy When the symptoms begin in adult life however the disease is often associated with a gastric ulcer or gastritis

Symptoms The clinical picture is indistinguishable from that of carcinoma gastritis or peptic ulcer with obstruction The predominant complaints are nausea and vomiting associated at times with vague atypical ulcer distress

Diagnosis Roentgen examination reveals a crescentic indentation of the base of the duodenal bulb produced by the markedly thickened pylorus This appearance frequently cannot be distinguished from that of hypertrophic gastritis an inflammatory reaction surrounding a pyloric ulcer or a scirrhous carcinoma *beginning in the pyloric end of the* antrum

Treatment Treatment may be unnecessary If a gastric ulcer is present the usual ulcer regimen is recommended Surgery should be considered when (1) histamine anacidity is present (2) there is no improvement in the emptying function after 2 to 3 weeks of medical management or (3) there is a reasonable doubt as to the nature of the lesion Subtotal gastrectomy may be necessary since it is as difficult to distinguish a benign from malignant involvement of the pylorus at the operating table as it is preoperatively

CONGENITAL ANOMALIES OF THE STOMACH

Congenital Hypertrophic Pyloric Stenosis of Infancy This disease is characterized by (1) hypertrophy of the pyloric muscle particularly the circular muscle layer and (2) spasm resulting in nar

rowing of the pyloric channel There is no histologic evidence of inflammation Males are affected four times as commonly as females

Symptoms Regurgitation and periodic vomiting herald the onset usually from 2 to 3 weeks after birth to 2 to 4 months The vomiting is often projectile without retching and is followed by rapid weight loss constipation and dehydration A milder clinical form may be seen if spasm predominates

Diagnosis Physical examination reveals visible hyperperistalsis dehydration and malnutrition A small mass the size of a marble or pea may be felt at the right rectus border beneath the costal margin In the milder form the hyperperistalsis and mass may not be evident Enlargement of the stomach and delayed gastric emptying confirm the diagnosis roentgenologically

Treatment An initial trial of medical management with frequent small feedings antispasmodics and correction of electrolyte and fluid imbalance is indicated If conservative treatment fails the Ramstedt operation consisting of a longitudinal incision through the pyloric muscle to the mucosa is recommended and is a uniformly successful procedure

Diverticula of the Stomach *Definition* A diverticulum is an abnormal outpouching or protrusion of the stomach wall forming a permanent sac True diverticula contain all the muscular coats within the wall of the pouch and are usually congenital False diverticula lack the muscular coats and are acquired as the result of pulsion or traction

Incidence Both congenital and acquired gastric diverticula are most often seen in middle aged women The posterior wall of the cardia near the lesser curvature is the most common site for the congenital type Acquired gastric traction diverticula are found most often near the pylorus and are caused by inflammatory or malignant involvement of adjacent organs Bezoars or trauma may produce pulsions diverticula

Duodenal diverticula are more common than gastric The congenital form is seen in the second and third portions of the duodenum Diverticula in the first part of the duodenum usually result from traction produced by a duodenal ulcer

Symptoms Diverticula rarely cause symptoms unless they become inflamed ulcerated or obstructed Associated diseases rather than diverticula may cause epigastric pain vomiting or bleeding

Diagnosis The diverticulum appears by roentgen examination as a barium containing sac projecting from the normal contour of the stomach or duodenum

Treatment Treatment is rarely necessary In selected cases excision or invagination of the diverticulum is indicated

MISCELLANEOUS DISEASES OF THE STOMACH

Prolapse of the Gastric Mucosa *Prolapse of the gastric mucosa* is a phrase used to describe the herniation of a portion of gastric mucosa through the pylorus resulting in a characteristic roentgen appearance It may occur at any age but is usually seen in the fifth decade occurring in 2 to 14 per cent of patients subjected to examination

Etiology The cause is unknown Herniation may be initiated by hyperperistalsis associated with antral gastritis duodenal ulcer or local spasm Excessive mobility of the mucosa upon the muscularis is a contributing factor as is submucosal edema from hypoproteinemia or cardiac failure

Symptoms Prolapse of the gastric mucosa usually produces no symptoms and is discovered as an incidental finding The symptoms attributed to this condition are nonspecific and are probably caused by the accompanying gastritis peptic ulcer or spasm Epigastric distress nausea vomiting weakness weight loss and bleeding have been described

Diagnosis The diagnosis of prolapse is suggested by the roentgen demonstration of (1) an "umbrella or mushroomlike defect in the base of the duodenal bulb and (2) rugae extending through the pylorus into the duodenal cap Gastroscopy usually reveals evidence of chronic hypertrophic gastritis

Treatment If symptoms are present a bland diet with antispasmodics may be prescribed Surgery (subtotal gastric resection) is rarely necessary

Foreign Bodies in the Stomach A wide variety of foreign bodies may be found in the stomach Small objects such as coins and marbles accidentally swallowed by children rarely cause symptoms and eventually pass through the gastrointestinal tract Sharp pointed objects (pins needles) may penetrate the wall of the stomach or intestine producing peritonitis or an abscess Large foreign bodies (spoons knives forks) found in the stomachs of the insane usually produce no symptoms although ulceration perforation or obstruction may occur

Bezoars are conglomerations of swallowed foreign material consisting of hair (trichobezoar) hair and vegetable fiber (trichophytobezoar) or of vegetable fiber alone (phytobezoar) The prolonged use of calcium or magnesium powders may give rise to concretions in the stomach (gastroliths) Bezoars may attain a large size producing symptoms simulating gastritis peptic ulcer cancer or pyloric obstruction They may occasionally simulate malignancy during roentgen examination

Treatment is indicated only when definite symptoms are present or when the foreign body presents a mechanical hazard Laparotomy with surgical re

moval may be necessary Metallic objects such as nails may be removed by means of a swallowed magnet attached to a string

Mycotic Infections of the Stomach Mycotic infections of the stomach include actinomycosis moniliasis (*Candida albicans*) aspergillosis and many others These infections frequently produce superficial or deep ulcerations of the stomach which may be single or multiple although they rarely penetrate or perforate The symptoms simulate those of gastritis ulcer or malignant disease of the stomach An examination of the vomitus or the gastric contents may reveal the fungus The treatment is that for fungus infections in general

Acute Dilatation of the Stomach Acute dilatation of the stomach is characterized by a rapid accumulation of large quantities (2 000 to 4 000 ml) of gastric and intestinal juices with marked gaseous distention of the stomach

Etiology The cause of the disease is unknown It usually occurs as a sequela of abdominal or pelvic operations or may follow abdominal trauma severe injury parturition or overeating It may complicate an acute infectious disease or be associated with uremia or marked electrolyte disturbances particularly potassium deficiency

Acute dilatation of the stomach has been attributed to the reflex inhibition of the gastric motor mechanism through efferent impulses reaching the stomach by way of the vagi and splanchnics The primary defect appears to be a loss of gastric tone followed by the swallowing of air and the accumulation of gastric and duodenal secretions which cannot be reabsorbed The gastric distention stimulates secretion further and produces pressure upon the third portion of the duodenum

Symptoms The onset is often insidious During the first 24 to 48 hr there is marked apathy and listlessness or epigastric fullness and constipation rarely with severe pain The epigastrium increases in size progressively but regurgitation and vomiting may not appear until tremendous distention has developed Although vomiting may become copious the stomach cannot empty completely Visible gastric peristalsis is absent because of gastric atony a succussion splash may be elicited Dehydration ensues associated with hypochloremic alkalosis tetany and uremia as a result of electrolyte imbalance Profound prostration collapse shock delirium coma and death follow

Diagnosis The flat roentgen film of the abdomen reveals a markedly dilated stomach filled with air and fluid permitting the differentiation from intestinal obstruction peritonitis and ileus

Treatment Treatment consists of continuous gastric suction for one day or more the administration of parenteral fluids and correction of electrolyte imbalance particularly potassium deficiency discussed in Chap 48 Recovery usually occurs if treatment is instituted promptly

Seymour J Gray

Definition A peptic ulcer is a benign sharply circumscribed defect or loss of tissue which extends into the muscularis mucosae or beyond and appears in areas of the alimentary tract bathed by acid pepsin gastric juice Gastric and duodenal ulcers

are considered together in this category for the sake of clarity although they may differ somewhat in regard to etiology clinical course and method of management Peptic ulcer is not merely a localized lesion of the stomach or duodenum it is a reflection of the sustained duress of our civilization manifested by emotional physiologic and biochemical aberrations which present a constant challenge to the internist psychiatrist and surgeon alike

Historical Background "Ulcer of the stomach" existed in ancient and medieval times Gastric hemorrhage was first described by Hippocrates (460 B C) In the fourth century B C Diocles of Carystos noted the adverse effects of emotional disturbances and military campaigns upon gastric ulcer A "non acid diet and sailing were recommended as treatment by Celsus in 20 A D Anatomic descriptions appeared as early as 1586 Morgagni in 1737 described perforation and gastrocolic fistula and the clinical pathologic correlations were established later by Baillie (1799) Abercrombie (1828) and Cruveilhier (1829)

Pathology The typical benign gastric ulcer presents a punched-out, sharply circumscribed lesion generally varying in size from 5 to 25 mm in diameter and from 5 to 20 mm in depth The defect appears round oval elliptical or rectangular with a flat, elevated or rounded edge depending upon the degree of edema Chronic gastric ulcers may measure 1 cm or more in depth because of thickening of the gastric wall Duodenal and jejunal ulcers are frequently smaller than gastric ulcers appearing from 2 to 10 mm in diameter and 1 to 5 mm in depth Gastric and duodenal ulcers are usually single They may occur simultaneously in both the stomach and duodenum and occasionally are multiple on the anterior and posterior walls of either organ when they are called "kissing ulcers"

Peptic ulcer begins as a penetrating process in the mucosa invading the deeper layers of the gastric wall sometimes perforating them completely It may be *acute* or *chronic* depending upon the amount of connective tissue present An *erosion* differs from an ulcer in that it involves only the mucosa and submucosa and does not penetrate into the muscularis mucosae

The base of the ulcer is usually covered by a grayish exudate of leukocytes and erythrocytes overlying a narrow layer of fibrinoid necrosis beneath which is a deeper zone of grossly red granulation tissue superimposed upon a fibrous tissue base of variable thickness The blood vessels are often thrombosed and the nerves in the scar appear edematous inflamed or necrosed The chronic ulcer undergoes repeated cycles of ulceration and healing accompanied by clinical exacerbations and remissions Scar tissue formation characterizes the healing process

Sites of Predilection Peptic ulcers occur in areas of the gastrointestinal tract exposed to the corrosive action of gastric acid and pepsin the lower esophagus stomach upper duodenum small intestine adjacent to a stoma produced during surgical anastomosis to the stomach or at the sites of heterotopic gastric mucosa in the lower end of the esophagus or in a Meckel's diverticulum The great majority of gastric ulcers are found along the lesser curvature of the stomach the *magenstrasse* a selectivity attributed by some to a diminished blood supply The pylorus itself and the immediate prepyloric area are also commonly involved Duodenal ulcers are usually found within the first 3 or 4 cm of the duodenum the duodenal bulb and are occasionally seen in the upper part of the second portion of the duodenum the so called "postbulbar" ulcer Benign gastric ulcer does not occur commonly on the greater curvature of the stomach

Incidence Approximately 10 per cent of the population develops a chronic gastric or duodenal ulcer during lifetime according to autopsy statistics It has been estimated that 1 to 3 per cent of the population above the age of twenty have some degree of peptic ulcer activity during any annual period Clinically duodenal ulcer is encountered four times as frequently as gastric ulcer although autopsy studies suggest an equal distribution

Sex There appears to be an increasing incidence of duodenal ulcer in males throughout the world since 1900 Duodenal ulcer is four times as common in men as in women although the male predominance is somewhat less in the gastric ulcer group

Age Peptic ulcer is most common between the ages of twenty and fifty although it may occur at any time Acute ulcers often multiple are seen in the newborn and perforation or hemorrhage may be the presenting symptom in the first decade of life The average age of onset for duodenal ulcer is thirty to thirty five years and for gastric ulcer thirty five to forty five years

Constitutional Type The typical ulcer patient has been classified as a tall lean hyposthenic individual Anthropometric measurements however have not been of significant predictive value and there is no specific constitutional type in this disease

Heredity Although hereditary tendencies to peptic ulcer have been noted in some families through one or more generations and ulcers have occurred in identical twins heredity does not appear to exert a primary influence

ETIOLOGY AND PATHOGENESIS

Chronic peptic ulcer in man develops presumably from a superficial erosion of a nonspecific type

Table 125 GASTRIC ACID PEPSIN AND UROPEPSIN IN NORMAL INDIVIDUALS AND PATIENTS WITH DUODENAL AND GASTRIC ULCER

	Average basal secretion mEq HCl/hr	Mean gastric pepsin units/hr	Mean uropepsin excretion units/24 hr
Normal person	1 5	18 000	3 670
Duodenal ulcer patient	5 6	50 600	8 470
Gastric ulcer patient	1 2	36 400	5 750

The acute ulceration may (1) heal promptly without scar formation (2) rapidly invade and extend through the entire gastric wall producing an acute ulcer with perforation or massive hemorrhage or (3) develop into a chronic ulcer

No single mechanism has been found for the transition of an acute erosion to an acute ulcer and its eventual development into a chronic ulcer The most pertinent factors are (1) gastric acid and pepsin (2) decreased tissue resistance (3) emotional and systemic stress

Acid Pepsin Factor Acid and pepsin are both essential to ulcer production Benign peptic ulcer occurs only in areas of the gastrointestinal tract *which are bathed by acid and pepsin and is not* found in pernicious anemia or in patients with persistent anacidity Peptic ulcer may be produced experimentally by stimulating gastric acidity with parenteral histamine in beeswax or by the continuous instillation of hydrochloric acid into the stomach

The average duodenal ulcer patient secretes acid at *more than three times the normal* rate during the basal fasting state the 12 hr nocturnal period after meals or following stimulation by histamine insulin or caffeine (Table 125) An increased secretory cell mass has been implicated A mean increase in gastric pepsin plasma pepsinogen and uropepsin is likewise seen in patients with duodenal ulcer and to a lesser extent in those with gastric ulcer Pepsin is always present in acid gastric juice acting upon cells which have been devitalized by the gastric acidity In gastric ulcer the free acid is not significantly elevated but is always present in sufficient amount to permit peptic digestion (Table 125)

Decreased Tissue Resistance The factors responsible for the tissue s resistance to ulceration are not known The *gastric mucus* acting as a barrier to ulceration as well as autodigestion may be altered or diminished *Lysozyme* a mucolytic enzyme in gastric juice does not affect the protective mucus barrier or play a significant role in peptic ulcer *Vascular factors* have been implicated because of the association of local ischemia congestion edema or venous stasis with emotional disturbances and ulcer formation It has been suggested that under conditions of stress local mucosal ischemia and ulceration may be produced by the shunting of blood through submucosal arteriovenous anastomoses Other contributing factors altering tissue resistance or increasing gastric secretion are exposure to cold anemia fatigue infections malnutrition dietary indiscretions and alcoholism

The Role of Physical and Emotional Stress in Peptic Ulcer There is considerable evidence that sustained emotional duress (anxiety fear worry and frustration) plays a significant role in the pathogenesis and recurrences of peptic ulcer Peptic ulcer appears to be a disease of civilization and is rarely seen among the natives in northern India Java and Sumatra or among the South African Bantus It is more prevalent in urban than in rural populations and among men with administrative and professional responsibilities although it occurs in all occupations and economic levels During the period of the heavy air raids on London the death rate from peptic ulcer increased as did the number of perforations and hemorrhages A similar trend was observed in Holland Sweden and Norway during the height of the war strain

Although there may not be a characteristic *personality or emotional pattern patients with peptic* ulcer have been described as overconscientious compulsive perfectionist aggressive tense stubborn critical competitive ambitious hard working and self assertive Their calm unruffled outward appearance belies the underlying suppressed mental agitation Alexander characterized the ulcer patient as a tense oral receptive" who is fundamentally dependent and wishes to remain in or revert to the infantile state This subconscious longing for the sheltered existence of the infant may manifest itself symbolically as a desire for food and milk The ulcer patient resents and is frustrated by this dependency and overcompensates by exaggerated aggression ambitiousness and independency

Hypersecretion of acid and pepsin accompanied by vascular changes within the gastric mucosa has been demonstrated during *emotional disturbance* (guilt hostility fear anger resentment and rage)

Mechanisms by Which Stress May Be Mediated to the Stomach The hypothalamus is the principal organ for the integration and transmission of emotional expression Systemic stress and emotional stimuli are expressed under cortical control through

the hypothalamus and may then be transmitted to the stomach by the vagus nerve or by an independent hormonal pathway relayed through the pituitary and adrenal glands

Hormonal Pathways Selected physical and emotional stress factors invoke a hypothalamic and pituitary response leading to the release of ACTH as part of the general adaptation syndrome ACTH in turn activates the adrenal cortex to release a number of steroid hormones including compound F which has a pharmacologic action similar to that of cortisone These adrenal steroids acting over a prolonged period may in some instances increase the gastric secretion of acid and pepsin or decrease mucus production and tissue resistance

Stimulation of the adrenal gland clinically with ACTH or the administration of adrenal steroids in therapeutic doses may in susceptible individuals (1) produce acute or chronic peptic ulcers with hemorrhage or perforation in patients with no previous peptic ulcer disease (Fig 176) (2) induce epigastric ulcerlike pain or (3) cause reactivation perforation or hemorrhage of a preexisting peptic ulcer

A relationship between the adrenal cortex and peptic ulcer is suggested by the extreme rarity of peptic ulceration and a decreased gastric secretory activity in untreated adrenal insufficiency Duodenal or gastric ulcers may develop however in patients with Addison's disease who are receiving maintenance cortisone therapy when the gastric secretory function is restored to normal Since adrenal hormone is presumably necessary for normal gastric function or for the initiation of the ulcerative process it has been postulated that the adrenal gland exerts a "permissive" action on the stomach sensitizing it to various ulcerogenic influences

Stress Ulcers Acute peptic ulcers with perforation or hemorrhage may result from increased vagal or adrenal activity or decreased tissue resistance on a vascular basis (1) *Curling's ulcer* following burns (2) *acute perforations* occurring after trauma shock or surgical procedures (3) *Cushing's ulcer* associated with intracranial diseases and (4) *air raid ulcers* are all examples of acute stress ulcers indistinguishable from those produced by the administration of adrenal steroids

Curling's Ulcer This is an acute ulceration occurring in the stomach or duodenum or both following extensive burns of the skin The lesions occur within a few days after the burn may be single or multiple and often bleed massively or perforate The ulcer may become chronic if the patient recovers A rapid increase in gastric secretion and uropepsin excretion coincides with a fall in eosinophils and increased excretion of 17 hydroxycorticoids in the urine Hemoconcentration histamine

Fig 176 Large chronic gastric ulcer 4 1 × 2 5 cm in diameter and 8 mm in depth on the posterior wall of the stomach lower third producing a massive fatal hemorrhage after 17 days of intravenous ACTH therapy (20 mg daily) A second smaller subacute ulcer 3 mm deep is seen at the left There was no previous ulcer history and routine roentgen examination of the stomach 1 year previously showed it to be normal.

release and vascular thrombosis contribute further to ulcer formation

Cushing's Ulcer This is an acute peptic ulcer with hemorrhage or perforation following brain tumors intracranial disease or brain surgery The increased gastric acidity accompanied by an elevated 17 hydroxycorticoid excretion in the urine suggests a hormonal adrenal pathway in addition to the neural mechanism

Adrenal Steroid Ulcers Acute ulcers with perforation or hemorrhage may occur during the administration of ACTH or the adrenal steroids in susceptible individuals The lesions may be single or multiple and are found in both the stomach and duodenum

ACTH and cortisone administered over a period of weeks may produce *chronic gastric or duodenal ulcers de novo* indistinguishable histologically from any other chronic peptic ulcer

SYMPTOMS OF PEPTIC ULCER

Epigastric Pain Epigastric pain is the most common presenting symptom of the uncomplicated peptic ulcer Ulcer distress may be identified by (1) rhythmic occurrence of pain following the ingestion

of food (or alkalies) (2) the character and location of the pain (3) periodicity and (4) chronicity

Mechanism of Ulcer Pain There is no unanimity of opinion regarding the cause of ulcer pain The inflammatory reaction in and around the ulcer may alter the pain threshold and increase its sensitivity Gastric acidity (chemical irritation) gastroduodenal spasm and changes in intravisceral pressure may be equally important

Rhythmic Pain Rhythmic pain following the ingestion of food or alkalies is observed in both gastric and duodenal ulcer first described by Moynihan as a food comfort pain comfort rhythm Ulcer pain almost never occurs in the morning before breakfast and characteristically appears when the stomach is empty 1 to 4 hr after a meal and persists for 30 to 60 min or more until food alkalies or water is taken Food or antacids in amounts adequate to buffer or neutralize the acid relieve the distress for 1 to 4 hr depending upon the amount ingested the rate of gastric emptying and the rate of gastric secretion

Pain after breakfast may be absent The distress is often more severe in the afternoon or between midnight and 2 A M when it awakens the patient and persists for an hour or more unless food or antacid is taken Nocturnal pain suggests hypersecretion with an acutely inflamed ulcer or pyloric edema spasm or stenosis The rhythm of gastric ulcer pain is usually less consistent than that of duodenal ulcer

Character of Ulcer Pain The character of the pain may vary in different individuals but is often described as burning gnawing cramplike aching cutting boring hurting annoying or as a hunger sensation or "gas pain" It usually persists as a steady continuous pain varying from 10 to 15 min to several hours or more differing from intermittent true hunger sensations The pain may vary from a dull ache to a sharp stabbing sensation depending somewhat on the patient s pain sensibility the extent of penetration inflammatory reaction and the location of the ulcer Uncomplicated gastric and duodenal ulcers rarely produce severe pain Duodenal ulcer pain may be more intense than gastric ulcer distress depending upon the level of gastric acidity and spasm

Duodenal ulcer pain is characteristically sharply localized to an area in the epigastrium approximately 1 in in diameter to which the patient points with the tips of two or three fingers in contrast to the generalized abdominal pain in many other forms of gastrointestinal disease The pain may radiate to the right costal margin the right lower quadrant the periumbilical area or through to the back Pain in the back usually but not invariably indicates chronic perforation into the head of the pancreas Gastric ulcer pain may be located in the left epigastrium while jejunal ulcer distress is more common in the midabdomen or left lower quadrant

Periodicity One of the most classic features of the peptic ulcer syndrome is the tendency for ulcer pain to disappear spontaneously for periods of 6 months to a year or longer The disappearance of symptoms is usually associated with a remission in the disease process and the recurrence of pain with a reappearance of the ulcer

Seasonal recurrences of peptic ulcer have often been noted in the late fall and early winter and again in the spring but these remain unexplained Fluctuations in gastric acidity corresponding roughly to the seasonal variation of the disease have been observed by Vanzant The influence of fatigue infection tension anxiety temperature changes and other forms of stress subject to seasonal variation may be significant Fluctuations in the threshold of adrenal activity and hormonal influences throughout the year may play a role although this has not as yet been proved

Chronicity The chronicity of the disease is often established by careful history In some instances the symptoms may have existed for only a few weeks particularly in the younger age group In others careful questioning will reveal an intermittent ulcer history of 10 to 20 years with many spontaneous remissions and exacerbations

Atypical Ulcer Symptoms When hypersecretion with gastritis duodenitis pyloric spasm or obstruction supervene ulcer pain may be only partially relieved by antacids or food Complete relief of pain follows aspiration of the stomach or more complete neutralization of the acid In some instances the discomfort is described as a *nausea sensation* *Vomiting* is rare in the uncomplicated ulcer and is often self induced to relieve pain A rare variant of the ulcer syndrome known as the *tabetic* or *biliary* type of pain is characterized by severe steady pain with persistent vomiting similar to that seen in biliary colic or tabetic crisis *Water brash* is an uncommon complaint of acid regurgitation and excess salivation occurring occasionally at night Other symptoms include gaseous discomfort or a cramplike distress when the stomach is empty *Constipation* and *irritable bowel symptoms* are common *Diarrhea* is rare except as a complication of gastrojejunocolic fistula *Weight loss* is unusual unless there is obstruction *Anemia* may develop gradually from chronic blood loss or acutely from massive hemorrhage

DIAGNOSIS

The diagnosis of peptic ulcer is made from the clinical history physical findings and particularly the roentgen or gastroscopic demonstration of the ulcer

Physical Examination The physical examination may reveal no significant abnormalities In some instances localized superficial or deep tenderness with muscle guarding may be elicited in the epigastrium between the xiphoid cartilage and the umbilicus A tender mass is rarely palpable The physical findings associated with perforation and obstruction will be discussed in the section on complications

Laboratory Examination Although the presence of free hydrochloric acid in the gastric contents is essential to the diagnosis of benign gastric ulcer instances of histamine anacidity with benign ulcers have been reported All lesions associated with persistent histamine achlorhydria should be considered malignant until proved otherwise The volume and concentration of gastric acidity in the individual patient, however is not diagnostic for either gastric or duodenal ulcer although the acidity is often increased in the latter Uropepsin excretion and plasma pepsinogen are significantly elevated in duodenal ulcer (Table 125) although they may be increased under other conditions as well Occult blood is frequently found in the gastric juice or stools of patients with active peptic ulcer The finding of sarcinae or yeast cells in the gastric contents suggests stasis and long continued obstruction Leukocytosis is sometimes observed particularly in the presence of vomiting dehydration or hemorrhage

Roentgen Examination The roentgen examination is the most valuable procedure in the diagnosis of peptic ulcer and constitutes an integral part of the examination of patients with epigastric distress

The visualization of a niche or crater in the stomach is pathognomonic of an ulcerating lesion Gastric ulcer appears as a smooth regular ulcer niche appearing in profile as a projection extending from the lesser curvature of the barium filled stomach (Fig 177) An active duodenal ulcer presents a crater and is usually seen *en face* as a sharply outlined, circumscribed collection of barium usually 2 to 10 mm in diameter standing out in contrast to the surrounding barium in the area (Fig 178) At times centrally radiating rugal folds converge to the site of the ulcer Craters may occur in the stomach duodenal bulb or the second portion of the duodenum The duodenal ulcer scar may contract one or both curvatures of the duodenal bulb producing a typical cloverleaf deformity (Fig 179) The healed gastric ulcer rarely distorts the stomach except in cases of chronic gastric ulcer when an hourglass deformity may result

Gastroscopic Examination The benign gastric ulcer appears as a sharply punched out lesion without evidence of nodularity or stiffness Its appearance may be helpful in distinguishing benign from malignant lesions Ulcers distal to the pylorus cannot be visualized gastroscopically

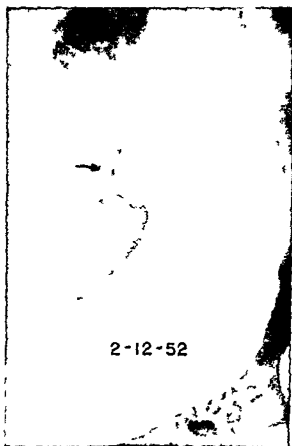

Fig 177 Large benign gastric ulcer on the lesser curvature of the stomach which healed completely in 10 weeks in a 6? year-old man The stomach was resected – months later because of an associated duodenal ulcer and revealed a small healed residual scar

The Differential Diagnosis of Benign from Malignant Gastric Ulcer The differentiation of benign from malignant lesions is often exceedingly difficult and depends upon a combined evaluation of all available clinical laboratory roentgenologic, and gastroscopic criteria The differentiation based on clinical history alone is usually not possible Although cancer often occurs in an older age group presents a shorter history or a change in character of the chronic distress none of these criteria is sufficiently distinctive in any individual to be diagnostic

The rhythmic postprandial distress with relief by antacids which characterizes the benign ulcer may occur with gastric cancer as well although complete relief of pain is uncommon Anorexia and weight loss occur more often in cancer usually late in the disease Vomiting of blood and melena are more common in ulcer but are not infrequent in cancer

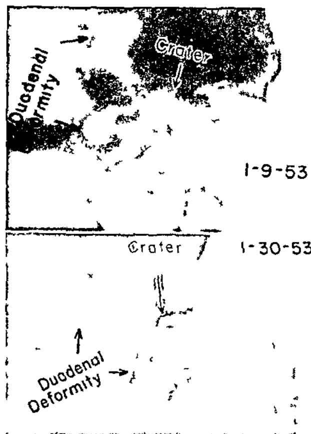

FIG 178 Large duodenal ulcer crater in a 52 year old woman demonstrating radiating folds duodenal deformity and pseudodiverticulum formation The crater healed in approximately 3 weeks

The presence or absence of anemia is not diagnostic of either disease

Laboratory Examinations Laboratory studies are helpful but often not conclusive *Persistent occult blood* in the stools after 2 or 3 weeks of treatment in a patient with a gastric lesion suggests malignancy although persistently negative stools are seen frequently with cancer Chronic gastric ulcer may also produce positive stools for occult blood intermittently for many weeks in spite of good treatment *A persistently low uropepsin excretion* is presumptive evidence of malignancy in a patient with a gastric lesion although a normal or high excretion does not exclude cancer (Table 124 Chap 244) *Persistent histamine anacidity* indicates malignancy although normal or high acidity may occur with cancer *Exfoliative cytology* may be exceedingly helpful in the diagnosis if tumor cells are found A negative cytology does not exclude malignancy

Roentgen Criteria Presumptive roentgen evidence of malignancy includes the following points

1 An ulcer crater surrounded by a collar of rigid tissue located beneath the contour of the lesser curvature with stiffness and induration on fluoroscopic examination (meniscus sign of Carman Fig 172 Chap 244) Edema and inflammation about a chronic benign ulcer may simulate malignancy although the ulcer niche of the benign ulcer usually extends beyond the level of the lesser curvature (Fig 177)

2 Ulcers on the greater curvature of the stomach are often but not invariably malignant

3 Stiffness and irregularity of the ulcer area

4 An ulcer associated with a filling defect marked rigidity or induration

5 Persistence of the ulcer or incomplete healing after adequate treatment

Benign lesions are characterized by the following

1 Converging or radiating folds to the site of the ulcer (in malignant lesions these are interrupted or absent)

2 Smooth contour and pliable sharp borders

3 Disappearance of the lesion on treatment with no residual evidence of ulcer infiltration or impairment of peristaltic activity

The size of the ulcer is of no diagnostic value large ulcers are frequently benign The site of the ulcer may be significant Lesions of the greater curvature are often malignant ulcers at the cardia have a greater incidence of malignancy than more distal lesions of lesser curvature Antral and pre

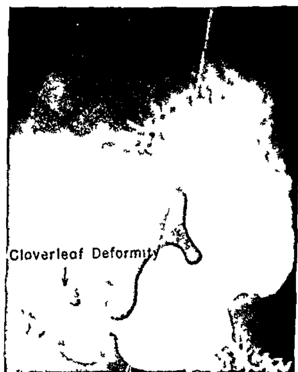

FIG 179 Typical cloverleaf deformity of the duodenal bulb with contraction of both curvatures produced by a duodenal ulcer scar

pyloric ulcers are often benign although predisposition of this area to malignancy has been reported

Gastroscopic Criteria Malignancy is suggested by (1) stiffness nodularity or induration of the ulcer edge (2) absence of a sharply demarcated clean-cut ulcer border resulting in blending with the surrounding mucosa (3) an elevated nodular stiff rolled up cuff of tissue surrounding the ulcer (4) absence of radiating folds and (5) extensive gastric atrophy These criteria are of presumptive value

Summary A definitive and unequivocal diagnosis of benign gastric ulcer cannot be made by the clinical history laboratory techniques or roentgen and gastroscopic examinations A reasonably accurate *presumptive* or *tentative* diagnosis of benign gastric ulcer can be made however by combining these diagnostic criteria The only conclusive evidence of a benign process is the complete healing of the ulcer by roentgen and gastroscopic examination (The management of gastric ulcer is discussed on p 1445)

Development of Cancer from Benign Ulcer Duodenal ulcers do not undergo malignant change Primary carcinoma of the first portion of the duodenum is exceedingly rare The possibility of malignant transformation of a benign gastric ulcer however cannot be categorically proved or refuted There is considerable evidence that a benign gastric ulcer very rarely becomes malignant In most instances the carcinomatous ulcer originates as a gastric neoplasm which undergoes ulceration as a result of peptic digestion or necrosis and simulates a benign lesion

Differential Diagnosis of Ulcer Distress A number of disease processes may simulate ulcer distress particularly if the symptoms are atypical (1) gastritis and duodenitis (2) hiatal hernia (3) gallbladder disease (4) coronary heart disease (5) carcinoma of the stomach or esophagus (6) esophageal ulcer (7) cardiospasm (8) irritable colon (9) pancreatitis (10) appendicitis (11) peptic ulcer in Meckel's diverticulum and (12) diseases of the kidney urinary tract and pelvic organs

Relationship to Other Diseases Peptic ulcer may coexist with many diseases except those associated with histamine achlorhydria such as pernicious anemia and extensive gastric atrophy It is rare in untreated Addison's disease a fact which emphasizes the significance of the hormonal mediation of stress to the stomach Peptic ulcer is rarely encountered in pregnancy although both hemorrhage and perforation may occur A healed doudenal ulcer deformity may be seen in patients with gastric cancer but the association of an *active* ulcer crater with a separate cancer is rare Peptic ulcer frequently occurs in patients with hiatal hernia and it may be increased with cirrhosis of the liver It is not more frequent in gallbladder disease diabetes and cardiovascular disease than in the population at large An increased incidence of peptic ulcer probably exists in polycythemia suggesting the relationship of vascular thrombosis to the pathogenesis of the disease

MEDICAL MANAGEMENT

A myriad of drugs and treatments are regularly heralded as "the ulcer cure" only to be added to a growing list of therapeutic failures Spontaneous periodic remissions in the disease process symptomatic improvement without ulcer healing and the psychologic benefits of an enthusiastic new therapeutic approach make clinical evaluation difficult Since no single etiologic factor in the pathogenesis of peptic ulcer has been established no ulcer cure may be anticipated The most satisfactory ulcer regimen is based upon a therapeutic approach to the secretory neurogenic hormonal and psychosomatic factors in the disease

General Principles of Therapy Therapy of peptic ulcer is directed to the healing of the ulcer and the prevention of recurrences Adequate acid neutralization at the ulcer site and attention to the physical and emotional stress factors which may promote acid secretion and spasm are the fundamental principles upon which effective ulcer management is based

Sippy's original premise that "the greatest known hindrance to the healing of peptic ulcer is the disintegrating and digestive action of the gastric juice" is still true Compounds designed to neutralize or inhibit the output of hydrochloric acid constitute a major part of the present therapeutic approach

Just as important as acid neutralization is the recognition by both the physician and patient of the psychologic and fatigue factors involved in the disease from the standpoint both of treatment and of prevention of recurrences The patient must be oriented to the chronicity of the disease and reeducated to "live with the ulcer" with minimal restrictions

Doctor Patient Relationship Successful therapy often depends upon an understanding physician who will help in coping with family difficulties poor eating habits sex problems financial worries adverse working conditions and social ambitions In selected cases formal psychiatric care including psychoanalysis may prove helpful but this is the exception rather than the rule Both psychotherapy and medication have a definite place in the management of peptic ulcer and the internist is qualified to administer both in most instances

Change of Environment Physical and mental rest are essential to healing The tense anxious and resentful patient may benefit from a short period of hospitalization or a vacation for 1 to 2 weeks Many patients do not require hospitalization or protracted removal from the home or work environment but are advised to interrupt *sustained* emotional stress and anxiety by frequent short vacations All patients with gastric ulcer should be hospitalized for a brief period to exclude malignancy by all available diagnostic procedures and to ensure the most rapid healing possible

Sedation Sedation in the form of phenobarbital in small divided doses throughout the day (15 to 30 mg) is very effective and should be part of the routine management Sedatives do not exert any direct effect on gastric secretion but they decrease the stream of impulses which pass from the higher centers of the brain to the stomach The new tranquilizing drugs (meprobamate) in small divided doses may be helpful also

Control of Gastric Acidity The aim of antacid therapy is the effective neutralization of gastric acidity and reduction in peptic activity Effective neutralization may be defined as the maintenance of the pH at 4 0 to 5 5

Aluminum Hydroxide The aluminum hydroxide preparations the safest and most satisfactory of the antacids in common use react with gastric hydrochloric acid to form aluminum chloride and water and are excreted in the feces as aluminum phosphate Although the final pH of the gastric juice usually does not exceed 4 0 aluminum hydroxide is an effective antacid demulcent and adsorbent

During the acute phase of ulcer disease liquid preparations in dosage of 15 to 30 ml hourly (or larger doses in cases of marked hypersecretion) are preferable Once the patient has become ambulatory the tablet form may be more convenient The dose varies from 2 to 4 tablets every 1 to 2 hr

Calcium Carbonate Calcium carbonate may prove beneficial in selected patients with marked hyperacidity and rapid gastric emptying who may not respond to the aluminum hydroxide preparations Hourly doses of 2 to 4 Gm are recommended Calcium carbonate is converted to calcium chloride in the stomach and excreted in the stools as relatively insoluble calcium phosphate and carbonate

Sippy Powders The Sippy powders neutralize gastric acidity more effectively than any other antacid they are prepared by mixing calcium carbonate and sodium bicarbonate in ratios of 1 1 to 1 4 They are usually administered in doses of 2 Gm hourly or every 2 hr

Other Antacids Numerous other preparations which inhibit pepsin activity or decrease gastric acidity by partial neutralization buffering and demulcent action or anion absorption have no advantages over the more effective less expensive antacids mentioned above These include magnesium trisilicate and carbonate protein hydrolysate sodium carboxymethylcellulose mucin anion exchange resins and detergents

Antacid Therapy Aluminum hydroxide preparations are not absorbed from the intestinal tract do not disturb the acid base balance and may be used safely in the treatment of most patients with peptic ulcer Calcium carbonate and the Sippy powders are contraindicated in the presence of (1) vomiting or repeated gastric aspirations (2) renal cardiac or liver disease and (3) hypertension because of the dangers of sodium absorption and hypochloremic alkalosis

The antacids should be administered at frequent and regular intervals since the rate of ulcer healing depends upon the duration and constancy of acid neutralization The antacids are prescribed at hourly intervals during the day and every 2 hours during the night with milk and cream feedings for the first week or two The management is not considered adequate unless the patient is completely free of pain When the symptoms subside antacid therapy may be administered at 2 hour intervals for 4 to 8 weeks until the ulcer has healed and is then prescribed four times daily between meals and twice in the evening particularly at bedtime All the antacids may produce severe constipation usually prevented by the use of magnesium oxide or carbonate (2 to 4 Gm) milk of magnesia (15 to 30 ml) or other mild cathartics

COMPLICATIONS OF ANTACID THERAPY *Fecal impactions* are common with all forms of antacid therapy particularly in the aged and bedridden and may be prevented by mild cathartics oil retention enemas and frequent rectal examinations

Hypochloremic alkalosis following vomiting or repeated aspiration of highly acid gastric juice containing 115 to 125 mEq per liter of chloride is seen in patients with gastric retention or obstruction Alkalosis from prolonged intake of absorbable alkalies such as the Sippy powders is becoming less common since the advent of aluminum hydroxide preparations and usually occurs in patients with previous kidney damage Symptoms of alkalosis are often absent although weakness lassitude headache loss of appetite nausea vomiting and clouding of the sensorium may be observed The blood carbon dioxide content is elevated and chlorides are depressed Secondary renal failure is manifested by a sharp rise in the blood urea nitrogen Treatment consists of discontinuance of alkalies and replacement of oral or parenteral chlorides and fluids discussed in Chap 48 In some instances of severe alkalosis the use of intravenous ammonium chloride has proved of great value A 2 per cent solution in distilled water or physiologic saline solution may

be administered slowly at a rate of not more than 200 ml per hr The use of ammonium chloride is contraindicated in the presence of liver disease

Renal calcinosis is a rare complication occurring in patients with previous kidney damage who take excess absorbable alkalies and milk for many years It is characterized by *hypercalcemia* without hypercalcuria or hypophosphatemia normal serum alkaline phosphatase renal insufficiency and alkalosis Treatment consists of avoidance of alkalies calcium restriction and forced fluids

Renal Calculi An increased incidence of renal stones following prolonged absorbable alkali therapy probably exists but has not been definitely established and is less common since the use of aluminum hydroxide therapy

Diet The ulcer diet consists of frequent regular feedings of small amounts of bland nonirritating foods the proteins of which buffer the hydrochloric acid and thus serve as effective antacids In addition to the milk proteins the hourly milk and cream feedings (Table 126 Ulcer Diet I) provide fat which supplies calories and reduces gastric secretion and motility In some instances whole milk or skimmed milk may be substituted for milk and cream and syrups or malt may be added for flavor If the milk or calcium intake must be limited as in patients with kidney stones or renal calcinosis gelatin or Jell-o may be substituted

The patient may complain of the monotony of this diet however and few need to be restricted to it for very long. Bread butter cereals cheese macaroni rice noodles potatoes eggs custards ice cream Jell-o and other soft foods may be added to or substituted for the hourly milk feedings from the start of treatment in many instances (Table 126 Ulcer Diet II) Regularity and frequency of meals are as important as the choice of food The diet is supplemented by vitamins

The patient is instructed to follow a specified schedule of feedings between meals individualized on the basis of his daily routine Unless the dietary pattern tastes food idiosyncrasies working hours and emotional factors are considered the patient will not follow a dietary regimen

During the healing process dietary discretion is difficult for many patients without the personal supervision and encouragement of the physician Gradual liberalization of the diet (Table 126 Ulcer Diets III and IV) to a three meal regime is recommended usually within 2 to 3 weeks The milk and cream or small feedings should be continued between meals together with the antacids After healing has occurred (4 to 8 weeks) a liberal bland diet is prescribed (Table 126 Ulcer Diet IV) with interval feedings three to four times daily

Alcohol a powerful stimulant of gastric acidity is not permitted during the active stages although

Table 126 ULCER DIETS

Ulcer Diet I

45 to 60 cc milk
45 to 60 cc cream (20% cream)
90 to 120 cc of above mixture every hour from 7 A M to 10 P M (1970 to 2660 cal 45 to 60 Gm protein)
If necessary additional feedings of 240 cc of the above mixture are given at 12 midnight 2 A M and 4 A M (950 additional calories 34 additional Gm protein)

Ulcer Diet II

45 to 60 cc milk
45 to 60 cc cream (20%)
90 to 120 cc of above mixture every hour from 7 A M to 10 P M
Small equal meals are given at 2-hr intervals from 8 A M through 10 P M Food is chosen from the following list
Cereals—refined or strained (Cream of Wheat oatmeal boiled rice)
Eggs—soft-cooked poached scrambled creamed
Toast or cracker—white only
Cheese—mild American cottage cream
Potato—white mashed or baked
Spaghetti noodles macaroni rice—all may be creamed au gratin buttered escalloped
Cream soups—strained
(rice pea potato celery mushroom spinach)
Jell-o custard plain puddings (butterscotch caramel tapioca Bavarian cream blancmange rice bread gelatin)
Vanilla ice cream
Butter or margarine

Ulcer Diet III

3 meals—8 A M 12 noon 6 P M—and 3 interval feedings—10 A M 3 P M 10 P M from the following list of foods
Cereal—refined or strained
Bread toast crackers—white light rye
Eggs—soft-cooked poached creamed scrambled
Cheese—mild American cottage cream
Meat poultry—ground beef veal lamb mutton broiled liver sliced turkey or chicken
Fish—fresh cod haddock sole halibut
Vegetables strained or puréed—asparagus carrots beet peas spinach green or wax beans squash
Potato white mashed or baked
Spaghetti noodles macaroni rice—all may be creamed au gratin buttered escalloped
Cream soups—rice pea potato celery mushroom spinach
Fruit soft-cooked canned or puréed—pears peaches *peeled apricots Royal Ann cherries* applesauce stewed apricots peeled apples prunes prune juice
Desserts—Jell-o custard puddings fruit whip ice cream, plain cake cookies (as listed in *Ulcer Diet II*)
Butter or margarine
One cup of coffee tea or Sanka
90 to 120 cc milk and cream mixture hourly between feedings or milk alone

Table 126 ULCER DIETS (*Continued*)

Ulcer Diet II

3 meals—8 A M 12 noon 6 P M —and 3 interval feedings—10 A M 3 P M 10 P M —from the following list of foods

Cereals—well cooked or refined ready to-eat

Bread toast and crackers—white and light rye fine graham

Eggs—soft-cooked or poached creamed scrambled

Cheese—mild American cottage cream

Meat poultry tender cuts baked broiled creamed roasted—beef steak veal lamb mutton liver turkey chicken

Fish—fresh cod haddock sole halibut (shellfish—optional depending on tolerance)

Vegetables—soft-cooked or canned (same choice as in Ulcer Diet III)

Potato—white mashed or baked

Spaghetti noodles macaroni rice

Cream soups—as in Ulcer Diet III plus any cooked vegetables as listed above

Fruits—soft-cooked or canned * (same choice as in Ulcer Diet III)

Desserts—same choice as in Ulcer Diet III

Butter or margarine

Tea coffee or Sanka

240 cc milk or milk and cream mixture every 2 hr between meals or as substitute for interval feedings

* Diluted orange juice after meals is optional

the tense individual with a healed ulcer may be allowed a very limited amount with meals

Coffee tea and chocolate are also stimulants of gastric acidity and should be restricted to a total of 1 to 2 cups daily with cream after meals During the acute ulcer phase a more strict limitation is advisable Decaffeinated beverages are well tolerated

Smoking There is no clinical or laboratory evidence that 8 to 10 cigarettes daily alter the course of the disease but excessive smoking should be discouraged particularly in patients with spasm or gastric retention The frustration of a habitual smoker deprived of tobacco may counteract the possible benefits to be derived from complete restriction In some patients however complete withdrawal is necessary

Aspirin may cause gastric irritation and should be avoided

Antisecretory Drugs A number of drugs are available which block the transmission of vagal impulses to the stomach and consequently reduce gastric acidity and motility These compounds supplement and complement antacid therapy

Atropine and *belladonna* are the most commonly used cholinergic blocking agents inhibiting the secretory and motor activity of the stomach The drugs appear to block the action of acetylcholine at the neurocellular junctions of the postganglionic vagal nerve endings Atropine is prescribed in doses of 0 3 to 0 6 mg and tincture of belladonna in doses of 8 to 20 drops in water (depending upon tolerance) four times daily before meals and at bedtime Inhibition of gastric secretion is usually accompanied by mild toxic symptoms such as dryness of the mouth or blurring of vision Full tolerance doses just short of these symptoms are desirable Numerous atropinelike compounds have been synthesized in an attempt to reduce the toxic side effects without altering the antisecretory activity These medications are generally more expensive and not more effective than atropine and belladonna Methantheline bromide (Banthine—50 to 100 mg four times daily) and propantheline bromide (Probanthine—15 mg four times daily) have no advantages over adequate doses of atropine

Dryness of the mouth blurring of vision tachycardia and urinary retention are the most common side effects Other toxic symptoms include drowsiness headaches constipation and manifestations of central nervous system stimulation This medication is contraindicated in coronary insufficiency cardiac disorders glaucoma and prostatic hypertrophy

Treatment of Intractable Ulcer Pain Patients may continue to experience ulcer pain in spite of a satisfactory dietary antisecretory and antacid regime Persistent intractable pain is usually associated with (1) an ulcer in the pylorus or duodenum (2) pyloric spasm edema or cicatrization (3) a penetrating ulcer and (4) marked nocturnal hypersecretion Additional measures are directed towards the removal or neutralization of gastric acidity

Gastric Aspiration Gastric aspiration is a most valuable adjunct to antacid therapy particularly in patients with night pain Continuous gastric aspiration for 24 to 36 hr is indicated in the presence of intractable pain with persistent vomiting or pyloric obstruction Prolonged aspiration is avoided because of the danger of hypochloremic alkalosis and because of discomfort to the patient

Soluble Alkalies Sippy powders or calcium carbonate (2 Gm every 1 to 2 hr) often relieves pain which has been intractable to aluminum hydroxide these soluble alkalies are useful for short periods in selected patients if there are no contraindications

Control of Nocturnal Secretion A marked increase in nocturnal secretion may produce night pain delayed healing gastric hemorrhage or perforation The pain is often relieved by administering aluminum hydroxide or the soluble antacids (Sippy powder calcium carbonate) at 2 hr intervals throughout the night with simultaneous feedings of 250 cc of milk and cream Atropine sulfate in doses of 0 6 to 1 mg at 6 00 P M and 10 00 P M and

nightly aspiration at 10 00 P M are particularly effective

Continuous Drip Therapy Continuous drip therapy is rarely necessary if the patient is awakened at 2 hr intervals during the night for regular feedings of milk cream and antacids In unusual instances where frequent feedings are refused food and antacids may be administered through a nasal catheter by a continuous drip The Winkelstein formula consists of 1 liter of milk containing 5 Gm sodium carbonate during every 8 hr period

Radiation Therapy Radiation therapy to the stomach *may inhibit gastric secretion* and facilitate healing in selected patients with intractable ulcer pain uncomplicated by pyloric obstruction Inhibition of gastric secretion is variable and usually not permanent *Two treatments are given* daily for 10 days through alternating anterior and posterior portals 13 cm square for a daily depth dose of 165 roentgens (r) (calculated in the midplane of the gastric fundus) and a total exposure of 1 650 r

Treatment of Gastric Ulcer All gastric ulcers should be considered potentially malignant until proved benign *A trial of medical management* for 4 to 8 weeks with sedation diet antacids and antispasmodics is justified when a classically benign gastric ulcer (by clinical roentgen and gastroscopic criteria) is found in a patient with free gastric acidity and a normal or high uropepsin excretion Hospitalization is usually advisable and *the course of the disease should be followed carefully* by repeated examinations

If the ulcer does not heal completely as shown by roentgen and gastroscopic examination after 4 to 8 weeks of satisfactory medical management or if abdominal pain or occult blood in the stools persists surgical exploration is indicated

Immediate surgery for gastric ulcer is recommended when (1) there is a reasonable doubt of the diagnosis clinically or by roentgen and gastroscopic examination (2) a meniscus sign or filling defect is present (3) the cytologic examination is positive (4) *histamine anacidity or a persistently low uropepsin excretion exists* (5) the ulcer is located on *the greater curvature of the stomach*

Subtotal gastric resection is the operation of choice for gastric ulcer and is indicated when the ulcer recurs under medical management or when there is difficulty in establishing the benign nature of the lesion The recurrence rate following resection for gastric ulcer is exceedingly low

Indications for Surgery Surgery is necessary in 10 to 20 per cent of patients with peptic ulcer because of intractability hemorrhage perforation or obstruction *In the uncomplicated duodenal ulcer* surgery is indicated when the patient appears unwilling or unable to follow an ulcer regime or when *frequent recurrences constitute an economic burden*

Subtotal gastrectomy for duodenal ulcer is the most satisfactory surgical procedure with a recurrence rate of approximately 5 per cent and a mortality rate of 2 to 3 per cent Gastroenterostomy *has been followed by recurrent ulcers in 20 to 30* per cent of patients in some series it is performed in elderly patients who are poor surgical risks or when a gastric resection is not feasible technically *Vagus section alone is not a satisfactory procedure* in view of the high incidence of recurrent ulcer (10 to 15 per cent) and other side effects Combination of vagus section with gastroenterostomy or gastrectomy is still being evaluated *The recurrent* ulcer rate is 5 to 15 per cent and will probably increase after a longer follow up period

Prognosis Approximately 80 per cent of ulcer patients respond satisfactorily to medical management over a period of years although the disease is characterized by remissions and exacerbations The *recurrence rate varies from 10 to 30 per cent* during the first year increasing thereafter by approximately 10 per cent each year depending upon emotional factors and the patient s adherence to a medical regime *Recurrences are attributed to fatigue* emotional and physical duress infections and indiscretions in diet alcohol coffee or tobacco

COMPLICATIONS OF PEPTIC ULCER

Perforation

Acute perforation is a serious complication occurring in 2 to 10 per cent of peptic ulcer patients and is a *common cause of death from this disease* It is exceedingly rare in women the male preponderance being 49 1 Perforation of a duodenal ulcer occurs nine times more commonly than that of a gastric ulcer *It may occur in any age group* but is usually observed in patients under forty five years The most common site of perforation is the *anterior wall of the duodenum*

A history of antecedent ulcer disease is present *in 75 per cent of cases* and *previous hemorrhage* is observed in 10 to 20 per cent Simultaneous hemorrhage and perforation are rare *Recurrent perforation* may occur in 1 to 5 per cent of perforated ulcers

Symptoms The perforation is heralded by a sudden agonizing excruciating pain in the midepigastrium accompanied frequently by collapse The pain *may remain localized but usually spreads to* the entire abdomen Radiation to the right *shoulder* may be present as a result of irritation of the diaphragm by free air or gastroduodenal contents Although the patient may be ashen gray and covered with a cold sweat as in surgical shock the blood pressure is usually normal and the pulse rate elevated *only slightly* Nausea and retching are

almost always present but vomiting may be a late symptom Body temperature at the onset is normal or subnormal

The patient lies "rigid and motionless The abdomen is immobile and the muscles are taut and rigid particularly in the upper portions producing classic boardlike rigidity The extent of rigidity depends upon the amount of gastric contents which has escaped into the peritoneal cavity Tenderness is usually generalized becoming most marked in the upper abdomen and occasionally spreading to the right lower quadrant as a result of drainage down the right lumbar gutter This localization presents the problem of differentiating perforation from acute appendicitis

After an hour or two the pain decreases muscle spasm remains the body becomes warm and the skin may regain its normal color If surgery is not performed at the end of 12 to 24 hr generalized peritonitis usually develops characterized by fever an increasing pulse rate leukocytosis and distention of the abdomen with loss of the boardlike rigidity but persistence of generalized tenderness

Physical Examination During the acute phase of perforation physical examination reveals in addition to the boardlike rigidity of the abdomen absent peristaltic activity and occasionally diminished liver dullness A subphrenic or subhepatic abscess may present itself 5 to 10 days following perforation as a mass or area of tenderness in the right upper quadrant accompanied by fever

Roentgen Examination Roentgen examination of the abdomen demonstrates pneumoperitoneum in more than two thirds of the cases of acute perforations best elicited if the patient is sitting up or lying on the left side for a few minutes prior to roentgenography Air when present is seen beneath the diaphragm or the lateral abdominal wall

Differential Diagnosis The most difficult differentiation is that of *acute pancreatitis* where there is usually more severe shock vomiting is more frequent and the abdominal rigidity is less intense and not boardlike Pneumoperitoneum is not present Pancreatitis is much more common in women than acute perforation A history of biliary tract disease is often present A markedly elevated serum amylase usually above 600 Somogyi units is frequently observed during the attack of acute pancreatitis although moderate increases in amylase may also occur with a perforated peptic ulcer Laboratory examination in acute pancreatitis may also reveal an increase in urinary diastase serum lipase blood sugar serum bilirubin or glycosuria

Acute appendicitis may be confused with perforated ulcer although the onset of pain is less sudden the rigidity is less intense and the past history of ulcer pain is often lacking There is no shoulder tip pain and the prostration is minimal Tenderness is maximal in the right lower quadrant less marked in the upper abdomen and may be present on rectal examination In *biliary or renal colic* the frozen attitude of the patient and the boardlike rigidity of the abdomen are absent If the gallbladder perforates the ensuing generalized peritonitis may mimic a perforated ulcer *Perforation of the gallbladder* however usually occurs during or after acute cholecystitis which first produces severe localized pain In *mesenteric occlusion* and *intestinal obstruction* the pain is often colicky and intermittent associated with some distention slight rigidity and more frequent vomiting The pain and tenderness of a *ruptured ectopic pregnancy* are usually in the lower abdomen and the rigidity is only moderate In *coronary occlusion* there is no marked rigidity of the abdomen and the pain radiates to the sternum neck and arms Abdominal rigidity is also absent in *gastric crisis* of tabes dorsalis The pain of *dissecting aneurysm* of the aorta is commonly substernal and intense *Diaphragmatic pleurisy* and *basal pneumonia* occasionally produce abdominal and shoulder pain associated with upper abdominal spasticity and tenderness but the cough fever increased respiratory rate and localization of pain to the upper abdomen are significant differential factors

Treatment Acute perforation constitutes a surgical emergency if the patient is seen within the first 24 to 48 hr after the perforation The mortality rate is lowest if surgery is performed within the first 6 to 12 hr Simple closure by suture with or without omental graft is the usual procedure Treatment for shock if present is instituted along with constant gastric suction antibiotic therapy and supportive electrolyte plasma and fluid administration

If more than 24 to 48 hr have elapsed after the perforation conservative management is generally recommended Decompression of the stomach with an indwelling tube is instituted at once and intensive chemotherapy is begun Similar conservative management is applied to patients in whom spontaneous closure of the perforation has already occurred as evidenced by the rapid disappearance of the pain the sharp localization of tenderness and rigidity and the excellent clinical state of the patient

Since the advent of antibiotics the mortality from acute perforation is probably less than 6 per cent Recently conservative management has been recommended as the definitive treatment for acute perforations and a mortality rate of 5 per cent or lower has been reported but the routine use of this form of therapy has not been widely accepted

Since perforation usually occurs in the severe

and often intractable forms of peptic ulcer with only 20 per cent remaining asymptomatic subtotal gastric resection as an elective procedure at a later date should be given serious consideration

Subacute and Chronic Perforations

Subacute and chronic perforations occur in the medial wall of the duodenum in contrast to the acute perforations of the anterior surface Consequently there may be little or no spillage of intestinal contents Free perforations into the peritoneal cavity occur but these are spontaneously sealed by fibrinous adhesions to the omentum liver and pancreas resulting in recovery without surgical intervention Diagnosis of these so called *forme fruste* perforations may be difficult since the symptoms are mild and atypical The patient may complain of sudden severe upper abdominal pain which within a few hours develops into a mild dull ache The amount of leakage is minimal producing a localized receding right upper quadrant peritonitis In some instances small abscesses may be formed at the ulcer site or under the diaphragm Physical signs consist of right upper quadrant tenderness and spasticity Roentgenograms may or may not show free air in the peritoneal cavity Many of these patients recover without any specific treatment although surgical intervention is recommended once the diagnosis has been made

In chronic perforation the capsule of the pancreas or liver or the transverse mesocolon or colon forms the base of the ulcer and no free perforation into the peritoneal cavity occurs Abscess formation is uncommon This type of perforation is rarely diagnosed except when a jejunal ulcer perforates into the colon producing diarrhea as the presenting symptom

Massive Hemorrhage

Approximately 20 to 25 per cent of all patients with peptic ulcer experience some degree of bleeding during the course of the ulcer Massive bleeding as hematemesis (vomiting of gross blood) or melena (tarry stools) occurs in 10 to 20 per cent of ulcer patients rarely in women Peptic ulcer is responsible for from 60 to 75 per cent of upper gastrointestinal bleeding

Contributing factors in massive gastric hemorrhage include alcoholism undue physical or emotional stress hypertension and arteriosclerosis excess aspirin intake infections fatigue dietary indiscretions and prolonged use of cortisone or adrenocorticotropic hormone

Pathology of Bleeding Ulcer Bleeding may be the result of ulceration into an artery vein or capillary Fatal hemorrhage is usually arterial in origin resulting from erosion into the pancreaticoduodenal gastroduodenal or gastric coronary artery or their larger branches A rigid arteriosclerotic vessel in the scar tissue of the ulcer base may be responsible for the fatal hemorrhage

Symptoms The signs and symptoms depend upon the severity of the hemorrhage the rate of bleeding and the suddenness of onset Hematemesis signifies a more rapid and extensive form of hemorrhage than melena Hematemesis is commonly observed in gastric ulcer but occurs in only 20 to 25 per cent of patients with duodenal ulcer Blood loss varies from the 60 ml necessary to produce a tarry stool to well over 1 000 ml The passage of a tarry stool may be the only presenting symptom since the loss of 350 to 500 ml of blood into the intestine may cause no significant change in the dynamics of the circulation if the hemorrhage has not occurred too rapidly

The symptoms following massive bleeding are faintness weakness dizziness headache perspiration thirst dyspnea syncope pallor and shock The pulse is usually rapid and weak The blood pressure is normal or low depending upon the patient's ability to compensate for the blood loss A persistently low blood pressure and a weak rapid pulse signify a dangerously massive hemorrhage

The initial hematocrit may be normal or elevated in spite of considerable blood loss since hemorrhage occurs at the expense of both the plasma and red blood cells The magnitude of the hemorrhage may not become evident for the first 12 to 24 hr depending upon the state of hydration and the rapidity with which the total blood volume is restored by dilution Blood volume measurements with radioactive chromium radioactive phosphorus or Evans blue dye indicate that 40 to 50 per cent of the total red cell mass may be lost without an initial parallel fall in the hematocrit

Leukocytosis as a reflection of hemorrhage is common An increase in the blood urea nitrogen (to levels of 30 to 50 mg per 100 ml) occurs within the first 24 to 48 hr resulting from (1) alimentary absorption of proteins from the digested blood (2) decrease in renal function as the result of shock and dehydration or (3) hypochloremic alkalosis from vomiting or ingestion of soluble alkalies The blood urea nitrogen is often a good index of the extent of the hemorrhage Fever is sometimes observed between the second and fifth day if a large amount of blood remains in the intestinal tract Digestion of blood in the gastrointestinal tract may elevate the blood ammonia level in the presence of extensive liver disease

Diagnosis Peptic ulcer is the most common cause of hemorrhage from the upper gastrointestinal tract

and should be considered first in spite of the absence of pain or an antecedent history Although previous episodes of hematemesis melena or ulcer pain are common silent bleeding with no antecedent ulcer distress occurs in 25 per cent of patients Acute ulcerations or erosions of the stomach and duodenum which are not seen roentgenographically cause bleeding of undetermined origin in approximately 15 per cent of patients

When the diagnosis is uncertain or the source of bleeding has not been established early roentgenologic examination within 24 to 48 hr of the onset of hemorrhage may be indicated if the patient is not in shock or bleeding massively Gastroscopic examination may be helpful in visualizing bleeding erosions and ulcerations which are too small to detect by roentgenography

Esophageal varices tumors of the stomach gastric polyps diaphragmatic hernia with localized gastritis gastritic ulcerations gastritis and blood dyscrasias are considered in the differential diagnosis

The string test may be valuable in determining the site of bleeding in patients with melena of obscure origin The patient is instructed to swallow a marked string which upon withdrawal several hours later is tested for blood or bile The site of bleeding may then be determined by measuring its position on the string in relation to the cardia and duodenum The cardia is approximately 16 in from the teeth the duodenum is designated by the bile stains Blood may also be demonstrated in the gastric contents obtained by gastric intubation

Laboratory aids in addition to the blood studies and blood urea nitrogen determination are the benzidine dihydrochloride test for blood and the uropepsin excretion which is invariably high in massive hemorrhage from peptic ulcer

Medical Management of Massive Hemorrhage *General Principles* Medical management of massive bleeding from peptic ulcer is based upon the (1) replacement of blood loss and treatment of shock (2) acid neutralization and maintenance of nutrition (3) reduction of the motor and secretory activity of the stomach and (4) supportive therapy

The patient should be seen at frequent intervals by a medical surgical team to evaluate the course of the hemorrhage The pulse rate and blood pressure reflect the rate and severity of the bleeding and should be determined at 30 to 60 min intervals in the acute bleeding phase

Replacement of Blood Loss and Treatment of Shock The treatment of shock consists of elevation of the foot of the bed the administration of mild sedation parenterally (such as sodium phenobarbital) and blood transfusions Blood transfusions are indicated whenever the (1) pulse rate exceeds 120 per minute or is rising (2) the blood pressure falls below 90 to 100 mm Hg or (3) evidence of shock is present Approximately 75 per cent of the estimated blood volume should be restored and the hematocrit maintained at 28 to 30 or above by repeated transfusions

Acid Neutralization and Maintenance of Nutrition Warm milk and cream in equal parts or whole milk in amounts varying from 30 to 120 cc as tolerated is administered hourly from 7 00 A M to 10 00 P M and at 2 hr intervals throughout the night as 200 to 250 cc feedings (Table 126 Ulcer Diet I) This supplies the patient with 2400 to 2800 cal and 60 to 70 Gm of protein daily Antacids are administered with the milk-and-cream feedings throughout the day and night Night feedings are necessitated by the marked increase in nocturnal gastric secretion An initial period of starvation with continuous gastric aspiration may be necessary for 24 to 48 hr if there is persistent nausea and vomiting during which the patient is maintained on parenteral fluids Small feedings of warm skimmed milk are then offered and the feedings are gradually increased as tolerated

The hourly regime is maintained for approximately 4 to 6 days until all evidence of active bleeding has disappeared The usual routine ulcer management is then instituted with an Ulcer Diet II (Table 126) supplementary small interval feedings and antacids Gastric aspiration roentgenography and gastroscopy may be performed safely at this time to determine the site and nature of the lesion

Small doses of sodium phenobarbital (0 03 to 0 06 Gm) and atropine (0 0006 Gm) are administered parenterally every 6 hr to reduce the motor and secretory activity of the stomach

Supportive therapy consists in the empirical administration of vitamins parenterally and the proper control of electrolyte and fluid balance Favorable results from the use of buffered solutions of thrombin or powdered Gelfoam have been reported but the substances are not in general use

Constipation and fecal impaction may be prevented by the proper use of cathartics and enemas Cold liquids morphine and aspirin should be avoided since they cause gastric irritation nausea vomiting and spasm

Surgical Treatment *Emergency Surgery* Every effort is made to terminate the bleeding by conservative means and to avoid delay of emergency surgery in those who will not respond to medical management The mortality rate of conservative treatment (2 to 5 per cent) is significantly lower than that of surgery performed during the active phase of bleeding (8 to 15 per cent)

Emergency surgery is indicated when the pulse

blood pressure or hematocrit cannot be maintained by the free use of blood transfusions (500 ml or more every 8 hr) and when bleeding recurs several days after recovery from a hemorrhage

The ulcer is removed surgically if possible When this is not technically feasible the ulcer bed is transfixed with ligatures or the branches of the gastroduodenal artery leading to the ulcer are ligated Subtotal gastric resection is then performed

Elective Surgery Elective surgery is indicated when the patient has suffered two or more hemorrhages while on satisfactory medical management or refuses to follow a medical ulcer regimen The procedure of choice is then subtotal gastric resection

Obstruction

Obstruction to the passage of food from the stomach may be caused by spasm edema inflammation or cicatricial stenosis resulting from an ulcer in the antrum pylorus or duodenum In some instances gastritis or hypertrophic pyloric stenosis may be contributing factors

Symptoms The clinical manifestations of duodenal obstruction include a feeling of fullness or nausea after meals followed by voluntary restriction of food and finally by vomiting There may be no pain or the ulcer pain may become severe and intractable to food or alkalies because of the retention of large amounts of highly acid gastric juice The vomiting may be minimal because of considerable decompensation and dilatation of the stomach

Diagnosis The diagnosis is best established by gastric aspiration and roentgenologic examination The degree and type of obstruction are ascertained by aspirating the stomach nightly (10 P M) after a 4 hr fasting period following the evening meal (6 to 10 P M) and measuring the volume of gastric content obtained Normally not more than 100 ml is present Retention of 150 to 400 ml usually signifies edema or spasm aspiration of 500 to 1 000 ml or more suggests cicatricial stenosis If the nightly retention of gastric juice gradually falls to normal after 7 to 10 days of medical management spasm or edema is likely In the presence of cicatricial stenosis high levels of gastric retention persist

Delay in stomach emptying may be demonstrated on physical examination by a succussion splash or by large gastric peristaltic waves moving from the left rib margin towards the right midabdomen

The roentgenologic examination gives the most accurate evidence of obstruction The site nature and extent of the obstructing lesion may be determined and the degree of retention and stenosis evaluated by measuring the channel fluoroscopically The lumen of the normal duodenal bulb has a diameter of 2 cm patients with marked cicatricial stenosis may present a channel of 2 to 4 mm or less Cicatricial stenosis is often accompanied by dilatation of the stomach and hyperperistalsis

Treatment The treatment depends upon the type and degree of obstruction If the obstruction is mild and edema or spasm is suspected nightly aspirations are not only helpful in evaluating the degree and persistence of the obstruction but constitute good therapy by removal of highly acid gastric juice Medical management alone is usually satisfactory if the obstruction has been caused by edema or spasm The patient may be maintained on an Ulcer Diet I or II (Table 126) with frequent soft feedings and antacids Surgery is necessary when gastric retention and obstruction persist after 7 to 10 days of medical treatment or when the fluoroscopic examination reveals cicatricial stenosis with a narrowed lumen

When the obstruction is marked decompression of the stomach by continuous gastric aspiration for several days is advisable Small liquid or semisolid feedings with discontinuation of suction for 2 hr or more after each feeding may then be attempted Replacement of chlorides and potassium is essential to prevent hypochloremic alkalosis during periods of gastric aspiration or vomiting Alimentation may be administered intravenously with the aim of correcting dehydration acid base imbalance and hypoproteinemia

Subtotal gastric resection is the procedure of choice for cicatricial obstruction but it should not be performed until the stomach has been adequately decompressed and the acid base balance corrected In some instances a posterior gastroenterostomy is preferable particularly in elderly patients who are not good surgical risks This procedure may be combined with vagotomy

Gastrojejunal Ulcer

A marginal peptic ulcer may develop at or near the site of anastomosis of the stomach and jejunum as a complication of gastroenterostomy or gastric resection and is usually seen on the jejunal side of the anastomosis

Incidence Gastrojejunal ulcer is seen more frequently after gastroenterostomy than following subtotal resection It is a rare complication of resection for gastric ulcer and practically never occurs after gastric resection for cancer

Symptoms Pain is the outstanding symptom It is ulcerlike in nature and is usually referred to the left midabdomen and periumbilical area Massive hemorrhage occurs frequently and may be the presenting symptom Chronic perforation into the colon producing a gastrojejunocolic fistula is not uncommon Acute perforation is rare

Diagnosis Recurrent atypical ulcerlike distress following an anastomotic procedure suggests the diagnosis The ulcer may be demonstrated roentgenologically or gastroscopically Failure to visualize the lesion does not exclude the diagnosis however

Treatment Intensive ulcer management should be instituted although surgery is often necessary When a marginal ulcer appears after a gastroenterostomy the gastroenterostomy may be undone and an adequate subtotal gastric resection performed In some instances a vagotomy alone is performed or the vagotomy may be combined with gastric resection The treatment of gastrojejunal ulcer developing after gastric resection is difficult This is the prime indication for vagectomy A higher and more adequate resection may be indicated in some instances

Gastrojejunocolic Fistula

This complication results from perforation of a marginal ulcer into the colon permitting food to pass directly from the stomach into the large intestine The symptoms are those of diarrhea containing undigested food belching of gas with a fecal odor loss of weight dehydration anemia and hypoproteinemia The diagnosis is made by observing the passage of barium directly from the stomach into the colon or from the colon into the stomach during a barium enema Treatment consists of surgical repair after the nutritional and electrolytic state of the patient has been improved or corrected

Postgastrectomy Syndrome

When the reservoir function of the stomach has been removed following a total or subtotal gastric resection the ingested food may enter the jejunum rapidly giving rise to a symptom complex called the *dumping syndrome* This complication may also be seen less frequently after a gastroenterostomy The symptoms consist of one or more of the following a feeling of faintness warmth weakness sweating vertigo palpitation nausea vomiting cramping abdominal or epigastric pain diarrhea and in some instances collapse The complaints may be extremely mild and barely discernible or they may completely incapacitate the patient persisting for weeks or years after the operation

The intrajejunal administration of hypertonic solutions may reproduce the symptomatology of the dumping syndrome Coincident with this are an acute decrease in the circulating blood volume resulting from the shift of plasma water into the intestinal lumen and electrocardiographic alterations attributed to sympathetic stimulation or changes in electrolyte balance Other contributing factors in the dumping syndrome may be (1) distention of the jejunum caused by fluid pouring into the lumen in response to the osmotic properties of the food (2) rapid changes in the blood sugar levels (3) vagal sympathetic imbalance (4) adrenal stimulation

Weight loss (or the inability to obtain the preoperative weight) is one of the most serious manifestations of the postgastrectomy syndrome and may be accompanied by anemia or a spruelike picture with diarrhea or steatorrhea The severity of these symptoms is related to the amount of stomach resected An iron deficiency has been demonstrated after partial gastrectomy and a vitamin B_1 deficiency after total gastrectomy

Treatment consists of (1) frequent feedings (2) a high protein high fat low carbohydrate diet (3) omission of fluids from meals (4) antispasmodics and (5) rest after meals Recently intravenous iron therapy has been recommended Injections of vitamin B_1 may also be helpful after total gastrectomy If marked weight loss persists in spite of dietary and medical management reoperation may be necessary in an effort to restore normal continuity

246 DISEASES OF THE DUODENUM AND SMALL INTESTINE

Thomas E Machella

DUODENITIS

The term *duodenitis* is applied to an inflammation of the mucosa of the bulbar region of the duodenum Such inflammation may be confined to this area or may be associated with a gastritis especially of the antrum It occurs in individuals subjected to emotional disturbances of the type encountered in peptic ulcer and in chronic superficial and hypertrophic gastritis The symptoms may be somewhat suggestive of a duodenal ulcer Massive hemorrhage may occur Gastric acidity is frequently increased The diagnosis is based on the demonstration of spasm and irritability of the duodenal cap on fluoroscopic examination on the presence of a coarse mottled appearance of its mucosa on the films and on the failure to demonstrate an ulcer crater When an ulcer type of pain is present in patients with such roentgen findings even though some of its features may be atypical an ulcer crater is not infrequently demonstrated at laparotomy or necropsy The treatment of duodenitis is similar to that of peptic ulcer

DUODENAL STASIS AND SPASM

Duodenal stasis and spasm most commonly occur as a result of disturbances in the motor function of the proximal duodenum in emotionally disturbed individuals In the usual case of duodenal stasis a to-and fro swaying of barium in the descending limb of the duodenum associated with delayed gastric emptying is observed during fluoroscopy The barium does not readily enter the transverse duodenum and occasionally refluxes into the stomach In more advanced cases the portion of the duodenum proximal to the vertebral column is greatly dilated and retentive Such an appearance is frequently ascribed to compression of the transverse duodenum by the mesenteric vessels It may be encountered in patients with disseminated lupus erythematosus In duodenal spasm the descending limb fails to fill out during the passage of barium and is visualized as a thin narrowed segment on the films

Symptoms first appear following the onset of an emotional disturbance They consist of a sense of epigastric fullness distention or pain belching anorexia nausea vomiting and headache Loss of weight may be considerable in those with marked stasis The pain which may be severe and colicky is likely to be precipitated or aggravated by ingestion of food and is often relieved by vomiting In duodenal spasm the pain may radiate around to the right costal margin and suggest biliary tract colic

The most important aspect of management in both duodenal stasis and spasm is the discovery and successful handling of the responsible psychogenic factors In the management of duodenal stasis the diet should consist of bland foods of high caloric content The feedings should be small and administered frequently Changes in posture such as lying on one side or the other for an hour after meals or assuming a prone position may relieve postprandial epigastric distress and facilitate emptying of the stomach and duodenum A cholinergic drug such as Urecholine administered preferably by injection will usually prevent the development of stasis if administered before meals or dispel it if given after At times a period of intravenous or intrajejunal alimentation may be required A short circuiting operation such as an enteroenterostomy invariably fails to afford relief unless the underlying psychogenic factors are meanwhile eliminated or an actual mechanical obstruction is present In the management of spasm of the descending limb as a result of either a motor disturbance or a duodenitis a similar dietary and psychotherapeutic regimen together with regular doses of phenobarbital and an effective antispasmodic should be prescribed

REGIONAL ENTERITIS

Regional enteritis occurs in both sexes and at any age The majority of patients are in the third and fourth decades when the diagnosis is first established The disease may be encountered in at least three clinical forms (1) during the first acute episode (2) after one relapse or more and (3) as a chronic affliction not infrequently complicated by obstruction or by abscess or fistula formation Though a lack of uniformity of opinion regarding the etiology of the disease exists accumulating clinical evidence strongly suggests that it is a psychosomatic disorder Emotionally the patients are and have been frustrated for one reason or another Unsatisfactory patient parent relationships often exist Emotional storms and upheavals precede the onset of the disease and the occurrence of relapses Most of the patients are very intelligent and are less dependent and more mentally mature than those with ulcerative colitis

Pathology The disease may be confined to the terminal ileum but may also involve additional segments or all of the mesenteric small intestine and at times the duodenum and/or the cecum and ascending colon In a small proportion of cases in

volvement of the terminal ileum is not demonstrable on roentgen examination or by gross inspection at laparotomy In rare instances the entire small intestine and colon are involved The nature of the pathology depends on the duration of the disease In the acute cases the bowel wall is thickened edematous and hyperemic Occasionally exudate is present on its surface and at times petechiae ecchymoses or small tuberclelike formations The mesentery is usually thickened and its fatty appendages may overlap the bowel The lymph nodes are usually enlarged and firm and varying amounts of free peritoneal fluid may be found In the chronic forms or following repeated relapses the wall of the involved intestine is greatly thickened as a result of edema cellular infiltration and fibrosis Miliary nodules containing epithelial round and giant cells may be found on the serosa Fistulous communications between loops of intestine and other viscera with or without abscess formation may be present

Clinical Picture The presenting symptoms are variable the manifestations may resemble those of acute appendicitis ulcerative colitis intestinal obstruction or a fever whose origin is not readily apparent Occasionally the outstanding manifestation is a massive hemorrhage especially when the jejunum and ileum are involved extensively in an acute process

In the typical acute case or during an acute relapse the symptoms and signs may be somewhat similar to those of acute appendicitis and the diagnosis is established at laparotomy In the chronic form a mild continuous or intermittent diarrhea accompanied by abdominal cramps and distention may be present over a period of months or years Severe diarrhea with bloody stools is more apt to be present when the distal colon is also involved Severe crampy pain in the right lower quadrant may be experienced when the terminal ileum is greatly stenosed particularly at the site of its junction with the colon Visible peristalsis may be detected when obstruction has occurred in such cases constipation and abdominal distention rather than diarrhea are complained of Fever is frequently but not always present It is intermittent in type and not always associated with diarrhea The fever is higher and more persistent when large areas of the small intestine are involved Anorexia nausea and vomiting may occur on a reflex basis as the result of actual obstruction or because of an associated chronic gastritis Manifestations of tetany on the basis of hypocalcemia are rarely encountered During the later stages of the disease a mass is frequently palpable in the right lower quadrant of the abdomen or elsewhere its shape depending on the number of adherent loops presence or absence of an abscess and fistulas and the location of the involved portions of the intestine Evidence of malnutrition including weight loss hypoproteinemia dependent edema and stigmas of vitamin deficiency may be present Complications include fistula formation abscesses at the site of perforation, intestinal obstruction occasionally arthritis and in the acute forms massive hemorrhage Fistulous communications may exist between loops of small intestine in apposition or between small intestine and the colon (especially the sigmoid) abdominal wall or various portions of the genitourinary tract including the bladder ureters and the uterus and fallopian tubes in females

Laboratory Findings Leukocytosis is usually present when the disease is active otherwise the leukocyte count is normal or even low Hypochromic anemia on a nutritional basis may occur and occasionally a macrocytic anemia The erythrocyte sedimentation rate is usually accelerated and the total circulating eosinophils are frequently reduced in the very ill patients Occult blood is found in the stool frequently and occasionally frank blood The latter is more frequently found when the colon also is involved

Roentgenologic Findings In the early stages of the disease roentgenologic changes may not be demonstrable and the examination of the small intestine may be reported as negative or as revealing an abnormal pattern not characteristic of any disease In more advanced stages the involved portion presents a characteristic appearance consisting of greatly narrowed segments of small bowel with dilated areas proximally Evidence of internal fistulas may be present The roentgen appearance of a narrowed terminal ileum is often referred to as the string sign Involvement of the terminal ileum is usually better demonstrated after a barium meal than after a barium enema as a diseased terminal ileum frequently fails to visualize during the latter examination Involvement of various portions of the proximal small intestine may at times be more clearly demonstrated by the small intestinal–enema technique or by the introduction of barium through a Miller Abbott tube into the segment under suspicion Associated involvement of the cecum and ascending colon are best demonstrated by a barium enema

Diagnosis The diagnosis in the acute case is usually made at laparotomy for suspected appendicitis The diagnosis in the chronic variety particularly when the terminal ileum is involved is not difficult when a young person with pain tenderness a mass in the right lower quadrant fever anemia weight loss and the characteristic roentgenologic findings is encountered Not infrequently an appendectomy scar is present A somewhat similar picture may at times be obtained when the

small intestine is involved by Hodgkin's disease primary sarcomatosis primary ileocecal tuberculosis sarcoidosis (Besnier Boeck Schaumann disease) endometriosis and by multiple carcinoids Chronic ulcerative colitis may be differentiated by the character of the stools the sigmoidoscopic picture and the barium enema Hodgkin's disease and primary sarcomatosis of the small intestine run a more severe and progressive course and give rise to rapid emaciation and gross hemorrhage Primary ileocecal tuberculosis is very rare in adults but occasionally occurs in children and adolescents Tuberculous involvement of the ileum is more frequently associated with evidence of tuberculosis elsewhere in the body particularly in the lungs Differentiation from sarcoidosis may not be possible clinically or by roentgenologic means The same applies to multiple carcinoids lymphosarcoma and endometriosis and microscopic examination must be resorted to Sprue usually can be readily differentiated by the clinical picture large frothy and foul smelling stools a macrocytic type of anemia a flat oral glucose tolerance curve and the failure of narrowed segments between dilated areas to persist during the course of the roentgen examination Actinomycosis of the ileocecal region with fistula formation to the external abdominal wall is readily differentiated by finding the characteristic granules in the discharging material

Treatment The type of treatment depends upon the stage and activity of the disease the location and extent of involvement and complications

Conservative management in the absence of obstruction or suppurative complication includes correction of existing deficiencies a high protein low residue diet supplemented with essential vitamins and iron and the discovery and successful handling of the emotional problems underlying the disease If a macrocytic anemia is present folic acid or vitamin B_{12} may be corrective Administration of ACTH or of cortisone has caused dramatic remission of symptoms and signs particularly in patients very ill as a result of toxemia or prolonged fever When cortisone is used it is effective by injection or by mouth and should be administered in large dosage (200 to 300 mg daily) during the first week or two When a favorable response is assured the dosage should be gradually decreased at weekly intervals over a period of 2 to 3 months until a state of good nutrition has been attained Thereafter it is cautiously discontinued In patients with advanced and extensive involvement maintenance therapy may be unavoidable if the patient is to survive When ACTH is used it is administered by intravenous or intramuscular injection in dosages of 20 to 30 mg twice a day for the desired period of time The possibility of an absence of the usual clinical signs of perforation and peritonitis during ACTH or cortisone therapy should be kept in mind After a remission has been induced situations which threaten the patient emotionally should be aborted or prevented so as to avoid relapses

Indications for surgery include intractability obstruction and perforation with abscess and fistula formation When surgery is contemplated the entire small intestine and colon should be re x rayed for detection of skip" areas of involvement if a long interval has elapsed between the initial examination and the decision to resort to surgery In some cases the length of involved intestine contraindicates surgical treatment A sigmoidoscopic examination should also be performed to rule out involvement of rectum and sigmoid Two types of procedure are used depending on the judgment or preference of the surgeon at the time of operation resection of the involved intestine or a short circuiting procedure A high incidence of relapses has followed both procedures usually because not all the diseased bowel wall was removed or short circuited In patients in whom the diagnosis of regional enteritis is made at operation for suspected appendicitis and the diseased segment is not excised it is well to remove the appendix in order to avoid having to consider the possibility of acute appendicitis during subsequent relapses

Prognosis A certain proportion of cases recover from the first acute attack and have no more subsequent symptoms Others experience subsequent relapses at irregular intervals or a chronic progression of the disease Some amazing recoveries have occurred in patients with extensive disease including some in whom the abdomen was explored and closed because the entire small intestine was diseased Death may occur from inanition or from shock and collapse following perforation and peritonitis or from pyemia and septicemia

ACQUIRED DIVERTICULA

Acquired diverticula of the small intestine occur as herniations of mucosa through weak points in the intestinal wall they are examples of pulsion diverticula They are encountered more frequently in the upper small intestine and less frequently as the terminal ileum is approached They are usually single and when multiple often occur in association with diverticula elsewhere in the intestinal tract Most of them are found in individuals beyond the age of fifty years

Uncomplicated acquired diverticula of the small intestine cause no symptoms as a rule The failure to empty properly may result in inflammation and give rise to symptoms including pain nausea vomiting and tenderness Perforation or hemorrhage may occur The sac may become strangulated and gangrenous and at times may be responsible

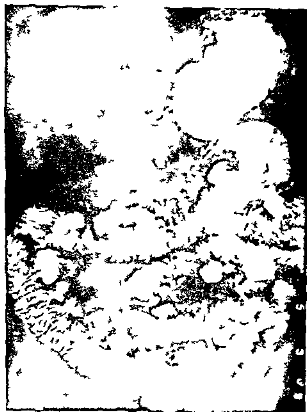

FIG 180 Roentgenologic appearance of the jejunum following ingestion of barium meal The barium filled sacs projecting from the intestine are asymptomatic diverticula

for partial intestinal obstruction Rarely a malignant tumor is found in a large diverticulum of the duodenum The diagnosis is made by roentgenologic visualization of the gut (Fig 180) As a rule no treatment is necessary Complications such as inflammation hemorrhage obstruction perforation or the presence of a tumor require appropriate medical or surgical measures

MECKEL S DIVERTICULUM

Meckel s diverticulum occurs as a result of incomplete obliteration of the omphalomesenteric duct, its structure depending on the degree of obliteration Its length varies from 25 to 125 mm The diverticulum is usually situated on the antimesenteric border of the ileum 25 to 100 cm above the ileocecal valve The lumen is lined with ileal mucosa but heterotopic tissue such as pancreatic cell rests or gastric colonic or duodenal mucosa may also be present The uncomplicated diverticulum usually is asymptomatic Complications include acute inflammation perforation intestinal obstruction volvulus intussusception peptic ulceration when heterotopic gastric mucosa is present and gross hemorrhage Benign and malignant tumors may originate in the diverticulum The roentgenologic demonstration of a Meckel s diverticulum is extremely difficult Most cases are first recognized at laparotomy performed for a suspected acute appendicitis or some other complication

TUMORS OF THE SMALL INTESTINE

All three types of tumor—carcinoma sarcoma and benign lesions—occur in the small intestine though rarely Malignant tumors may reach considerable size are usually single and spread by lymphatic metastasis or direct invasion Benign growths are often polypoid sometimes multiple and usually but not always smaller than malignant tumors

The most common location of carcinoma is the second portion of the duodenum and the next most frequent is the lower ileum Adenocarcinoma occurs more frequently in the duodenum while the scirrhous or "napkin ring" type of carcinoma is more often found in the lower ileum Bleeding gross or microscopic is the most important clinical manifestation The presenting symptoms may also be those of mechanical obstruction and rarely of perforation Metastasis occurs early and recurrence within a few months after resection is the rule

The most common sites of sarcoma are the terminal ileum and jejunum Pain is a frequent symptom The tumors tend to grow externally and are less apt to ulcerate so that bleeding usually does not occur Mechanical obstruction may occur as a result of either distortion of the lumen or infiltration of the bowel wall Ascites may develop as a result of mesenteric or peritoneal involvement or of pressure on the main venous trunks

The most frequent sites of benign tumor are the ileum and the duodenum Adenomas are the most common and myomas are next in frequency with fibromas and lipomas slightly less prevalent About one half these tumors give rise to symptoms as a result of hemorrhage obstruction or intussusception

The discovery of all three types of lesions is made by roentgenologic means Often special intubation procedures may be required The exact type of lesion is determined by microscopic examination after surgical resection

CARCINOID (Argentaffinoma)

Carcinoid is a relatively rare tumor It is found most frequently in the appendix and terminal ileum but may be encountered anywhere in the gastrointestinal tract between the stomach and rectum It arises from chromaffin cells and is a potentially malignant tumor Metastases may occur to the regional nodes peritoneal cavity pancreas liver and bile ducts The tumor as well as its metastases

is capable of liberating serotonin (5-hydroxytrypta mine) a derivative of tryptophan which has a stimulant effect on various smooth muscle systems including the blood vessels gastrointestinal tract bronchi and estrual uterus and may also play a neurohumeral role in the central nervous system The normal blood level of serotonin is 0 2 to 0 4 µg in the presence of carcinoid it may be as high as 4 µg The normal urinary daily output of 5 hydroxyindoleacetic acid the form in which serotonin is eliminated in the urine is 3 to 8 mg while in the presence of carcinoid it may be as high as 350 mg

Carcinoid may cause local manifestations similar to those caused by other tumors of the intestinal tract including intestinal obstruction In addition it may give rise to certain systemic manifestations as a result of the pharmacologic action of the serotonin their nature depending on the susceptibility of the various smooth muscle systems to serotonin as well as to variations in local concentrations of antagonistic compounds These manifestations are usually mild at first but gradually increase in severity over a period of several years as a result of growth and spread of metastases Earliest symptoms include episodes of palpitation stiffness or swelling of face and diarrhea the latter as a result of increased intestinal motility Later spells of tenseness weakness and nausea are complained of Still later the patient experiences episodes of flushing of the skin especially of the face lasting a minute or two attacks of respiratory distress varying from mild dyspnea to wheezing and asthma spells of hot and tingling sensations in the hands and feet transient dysphagia abdominal cramps borborygmi and expulsion of flatus and watery stools In advanced cases attacks of a shocklike picture may develop These consist of weakness abdominal pain extreme cyanosis cold and wet skin and an inability to obtain the blood pressure and pulse Breathing may cease and artificial respiration may be necessary Such syncopal episodes have been precipitated by squeezing a large tumor during physical examination or at laparotomy consequently carcinoid lesions should be palpated gently Other manifestations may include cutaneous telangiectasia injection of the sclerae extreme cyanosis during the flushing episodes eventually leading to a reddish hue of the face with thickening of the skin The latter is not accompanied by polycythemia

The right side of the heart may be involved especially in patients with hepatic metastases The pathologic changes in the endocardium are somewhat similar to those found in the left side of the heart in fetal endocardial fibroelastosis The thickened endocardium consists of spindle shaped fibroblasts located in an edematous stroma but with no elastic tissue and very little collagen Intimal changes may be present in the coronary arterioles similar to those of endarteritis

The prognosis is usually good even in the presence of regional metastases The primary lesion as well as resectable metastases should be excised With resection of the primary lesion the patient may live 10 to 12 years Levels of serotonin in the blood and of 5 hydroxyindoleacetic acid in the urine return to normal after excision of the primary tumor and its metastases It is very likely that compounds capable of neutralizing the effects of serotonin may eventually be developed which will control some of the clinical manifestations

247 APPENDICITIS

Thomas E Machella

ACUTE APPENDICITIS

Incidence Acute appendicitis can occur at any age but is most often seen between the ages of ten and thirty years It has been estimated that 1 8 per cent of the total population of the United States undergo appendectomy yearly

Etiology The pathogenesis of appendicitis has not been settled to the satisfaction of all Some maintain that the disease is primarily of bacterial origin the bacteria reaching the appendix through its blood supply (hematogenous) or by lodgment in its crypts of swallowed microorganisms (enterogenous) Others maintain that obstruction of the lumen occurs first and that inflammation is secondary The latter is a more likely explanation The anatomic nature of the appendix itself is such that substances which enter it may find difficulty in leaving Though a large variety of mechanical factors can constitute physical handicaps for ready evacuation of the appendix an appendicolith is probably the most important single cause of obstruction of the lumen One or more are found in 50 to 60 per cent of cases of appendicitis Sometimes swallowed foreign bodies such as pins small

bones or lead shot may lodge in the appendix and give rise to obstruction and even perforation of its wall Occasionally worms especially *Enterobius vermicularis* and sometimes *Ascaris lumbricoides* may lodge in the appendix and provoke colic Following obstruction due to any cause the secretory pressure of the appendix produces injury to the tissue with leukocytic invasion pus formation and subsequent gangrene and perforation

The results of bacteriologic examination of the contents of inflamed appendixes vary Undoubtedly the streptococcus plays an important role in the etiology The fact that colon bacilli may rapidly overgrow other organisms may account for the significance sometimes ascribed to their presence Other organisms including anaerobes have been recovered from inflamed appendixes

Clinical Picture The typical attack of appendicitis is characterized by intermittent or colicky pain in the epigastrium or periumbilical region at times generalized but tending shortly after to become localized in the right lower quadrant The onset of the pain is frequently followed by nausea and/or vomiting Anorexia is common it may precede the pain or it may come on with nausea and vomiting Localization of the pain in the right lower quadrant is associated with a change in its character It becomes dull and constant and then gradually increases in severity nausea and vomiting tend to subside Complete obstruction of the lumen is usually associated with pain of a colicky nature The painful episodes are of short duration but recur with increasing severity Cessation of pain may indicate expulsion of an obstructing substance from the appendix into the lumen of the gut but also like the calm before the storm may herald the onset of gangrene and perforation with subsequent peritonitis

In the usual case the temperature rarely exceeds 100 F When gangrene develops it may reach 101 F Perforation and peritonitis are usually associated with still higher temperatures An increased pulse rate is usually present but rarely exceeds 100 per minute unless gangrene or perforation occurs Children are apt to have a higher fever and pulse rate than adults In the latter group both temperature and pulse rate may be normal Constipation occurs in about 15 per cent of the patients during the acute symptoms while diarrhea is less common The incidence of diarrhea in children is difficult to assess as not infrequently laxatives have been administered

The most important physical sign of acute appendicitis is tenderness over the site of the appendix this usually coincides with the region in which the pain localizes The tenderness becomes more diffuse and localization difficult when peritoneal irritation spreads Rebound tenderness may be elicited when the parietal peritoneum is involved in the inflammatory process Rigidity of the abdominal wall may occur as additional evidence of peritoneal irritation Rectal examination with the patient in the left lateral position may elicit tenderness in the right pelvis

Laboratory Findings The leukocyte count is usually elevated the degree of leukocytosis depending on the severity of the inflammation and the presence or absence of suppurative complications It may vary from 10 000 in mild cases to over 20 000 per cubic millimeter when peritonitis is present A normal leukocyte count, however may be encountered even in patients with severe inflammation but in such cases the differential count will usually reveal a marked increase in the number of immature neutrophils as well as an increase in the total number of cells of the myeloid series Children tend to develop a greater leukocytosis than adults

Urinalysis should be performed in all instances of suspected appendicitis and should be especially examined for red blood cells leukocytes bacteria and sugar Barium enema is contraindicated when acute appendicitis is suspected

Complications Peritonitis is a dreaded complication of appendicitis Its presence is usually heralded by an increase in the area of pain tenderness and rigidity and subsequently by abdominal distention and cessation of peristalsis Fever and leukocytosis increase as the process spreads

Perforation of the appendix with extrusion of pus into a pocket formed by adhesions results in an abscess The localization of pain and tenderness which have been diffuse and a lessening of fever and degree of leukocytosis with a restoration of a number of mature neutrophils indicate that the infection has become localized with abscess formation Abdominal palpation may reveal an indefinite tender mass which may also be palpated by rectum When the abscessed wall includes part of the cecum sigmoid renal pelvis urinary bladder, ureter or vagina fistula formation may result A sinus may occur if the content of an appendical abscess finds its way to the skin surface Other complications include suppurative pylephlebitis liver abscess subdiaphragmatic abscess pulmonary embolism adynamic ileus and partial or complete intestinal obstruction as a result of adhesions

Diagnosis The occurrence of epigastric hypogastric or periumbilical pain with subsequent localization in the right lower quadrant associated with nausea and vomiting and tenderness in the right lower quadrant justifies the diagnosis of acute appendicitis Individuals with disease of the spinal cord from any cause when developing acute appendicitis may demonstrate none of the clinical manifestations to point to the appendix as the cause of illness In the aged in whom the primary

process is sometimes vascular occlusion there is little or no antecedent colic The process remains almost asymptomatic until local or general peritonitis sets in

A careful history must be elicited in cases presenting atypical features as appendicitis can simulate almost any acute disease of the abdomen A retrocecal appendix may give rise to pain in the right flank or costovertebral area Location of the inflamed appendix on the psoas muscle may give rise to pain on the anterior and inner aspects of the thigh when the hip is moved Contact with the ureter may give rise to dysuria or frequency microscopic hematuria and radiation of the pain into the genitalia or inner aspects of the thigh Pain low in the back or in the perineum as well as pain on defecation may occur when the appendix is in contact with the sigmoid Left sided appendicitis in older persons may be mistaken for acute sigmoid diverticulitis

Differential Diagnosis The differential diagnostic possibilities include mesenteric lymphadenitis diverticulitis of the cecum or sigmoid carcinoma of the proximal colon and cecum Meckel s diverticulitis regional enteritis acute gastroenteritis urinary tract disorders such as ureteral calculus pyelitis or hydronephrosis of a low lying kidney an inflamed low lying gallbladder perforated peptic ulcer abdominal pain of diabetic acidosis perforation of the cecum secondary to a local carcinoma or an obstructing lesion in the sigmoid or a ruptured diverticulum pelvic inflammatory disease rupture of a graafian follicle ruptured ectopic pregnancy torsion of a pedunculated uterine fibroid or of a small ovarian or paraovarian cyst or of an ovary with a long attachment abdominal crises of tabes rupture of the deep epigastric artery incarcerated inguinal or femoral hernia sequelae of abdominal trauma orchitis in an undescended testis mesenteric occlusion acute porphyria intestinal obstruction abdominal vein phlebitis abdominal colic of plumbism and polyarteritis nodosa

In the final analysis a great variety of extra appendical diseases and lesions may mimic the signs and symptoms of acute appendicitis The mortality of delay is so great as compared to the mortality of a simple appendectomy that one is justified in resorting to laparotomy when there is any reasonable doubt as to the diagnosis Time has not altered the old adage a live patient without an appendix is much better off than a dead person with one

Treatment The treatment of the acutely diseased appendix consists of its removal as soon as the diagnosis is suspected and the patient adequately prepared The time at which surgery should be performed in the presence of complications of appendicitis is a matter for decision in the individual case The administration of cathartics to patients with suspected appendicitis is contraindicated

"CHRONIC" APPENDICITIS OR APPENDICLAUSIS

The term *chronic appendicitis* has been loosely employed to indicate two different entities One is recurrent acute appendicitis which has already been discussed except for the feature of recurrence The other use of the term chronic appendicitis is largely incorrect it has been applied to unexplained persistent symptoms referable to the right lower quadrant resulting from almost any cause but usually due to an irritable cecum secondary to emotional disturbances Patients in the latter category are often made worse by removal of the appendix and are rarely relieved except for psychotherapeutic effect In the absence of clear evidence pointing toward an acute attack operation for *chronic* appendicitis is unjustified

248 DISEASES OF THE COLON AND RECTUM

Seymour J Gray

The diagnostic approach to the patient with colonic and rectal disease is predicated upon the integration of a careful history and physical examination with properly selected laboratory procedures proctosigmoidoscopy and roentgenography

Symptoms such as constipation diarrhea change in bowel habit rectal bleeding abdominal pain nausea vomiting and weight loss are of particular diagnostic significance The frequency and character of the evacuations and the presence of gross blood melena mucus or pus in the stools deserve

bones or lead shot may lodge in the appendix and give rise to obstruction and even perforation of its wall Occasionally worms especially *Enterobius vermicularis* and sometimes *Ascaris lumbricoides* may lodge in the appendix and provoke colic Following obstruction due to any cause the secretory pressure of the appendix produces injury to the tissue with leukocytic invasion pus formation and subsequent gangrene and perforation

The results of bacteriologic examination of the contents of inflamed appendixes vary Undoubtedly the streptococcus plays an important role in the etiology The fact that colon bacilli may rapidly overgrow other organisms may account for the significance sometimes ascribed to their presence Other organisms including anaerobes have been recovered from inflamed appendixes

Clinical Picture The typical attack of appendicitis is characterized by intermittent or colicky pain in the epigastrium or periumbilical region at times generalized but tending shortly after to become localized in the right lower quadrant The onset of the pain is frequently followed by nausea and/or vomiting Anorexia is common it may precede the pain or it may come on with nausea and vomiting Localization of the pain in the right lower quadrant is associated with a change in its character It becomes dull and constant and then gradually increases in severity nausea and vomiting tend to subside Complete obstruction of the lumen is usually associated with pain of a colicky nature The painful episodes are of short duration but recur with increasing severity Cessation of pain may indicate expulsion of an obstructing substance from the appendix into the lumen of the gut but also like the calm before the storm may herald the onset of gangrene and perforation with subsequent peritonitis

In the usual case the temperature rarely exceeds 100 F When gangrene develops it may reach 101 F Perforation and peritonitis are usually associated with still higher temperatures An increased pulse rate is usually present but rarely exceeds 100 per minute unless gangrene or perforation occurs Children are apt to have a higher fever and pulse rate than adults In the latter group both temperature and pulse rate may be normal Constipation occurs in about 15 per cent of the patients during the acute symptoms while diarrhea is less common The incidence of diarrhea in children is difficult to assess as not infrequently laxatives have been administered

Diagnosis The occurrence of epigastric hypogastric or periumbilical pain with subsequent localization in the right lower quadrant associated with nausea and vomiting and tenderness in the right lower quadrant justifies the diagnosis of acute appendicitis Individuals with disease of the spinal cord from any cause when developing acute appendicitis may demonstrate none of the clinical manifestations to point to the appendix as the cause of illness In the aged in whom the primary

spective high pressure" emotionally labile individuals Other contributing factors are laxative abuse irritating enemas tobacco excess and coarse food Ice cold or hot liquids may activate the gastrocolic reflex in susceptible individuals and invoke mass peristalsis colonic spasm or diarrhea The irritable colon is often seen as a residual following food poisoning or specific dysentery infections Food allergy is rarely involved

Pathologic Physiology The motor and secretory activities of the colon are controlled by the autonomic nervous system The gastrocolic reflex mediated through the vagus nerve plays a significant role in initiating mass peristalsis Increased parasympathetic activity accelerates the motor and secretory responses while overbalance of the sympathetic system inhibits the activity of the colon Normally a fine balance between the two systems permits the orderly progression of intestinal contents and gas through the intestinal tract without sensory perception or distress

As a result of autonomic imbalance in the emotionally disturbed patient the motor secretory and vascular responses of the colon are no longer properly integrated and provoke a multitude of gastrointestinal complaints

The principal functions of the colon are (1) absorption of water and electrolytes with dehydration of the fecal contents and (2) formation of a reservoir for the colonic contents to permit orderly evacuation

Constipation results from decreased intestinal motility colonic spasm and increased water absorption *Diarrhea* is caused by hypermotility of the colon and a reduced absorption of water resulting in the rapid transit of the liquid colonic contents Intermittent periods of hypomotility and hypermotility are reflected by *alternating constipation and diarrhea*

Distention of the bowel with gas and colonic spasm produce *abdominal pain* An increased secretion of *mucus in the stools* may be a manifestation of emotional disturbances or of chemical bacterial or mechanical irritation

Abdominal distention and rumbling and gurgling of the bowel are produced by excessive gas hyperperistalsis and hypertonicity Increased gas is caused by (1) excessive swallowing of air (2) abnormal fermentation of carbohydrates (3) interference with the intestinal absorption of gases (4) constipation hypomotility or spasm (5) interference with digestion of certain high carbohydrate foods rich in cellulose and (6) interference with the venous circulation Flatus consists mainly of nitrogen in addition to carbon dioxide oxygen and methane

Symptoms The symptoms of the irritable colon vary considerably depending upon which of the previously discussed disturbed physiologic mechanisms is dominant The most common manifestations are abdominal distress distention constipation diarrhea excess mucus secretion and neurocirculatory instability One symptom may replace another as exemplified by alternating constipation and diarrhea

Abdominal distress the most frequent complaint may consist of (1) a sensation of abdominal fullness and discomfort (2) severe regularly recurring cramplike pain (3) a deep dull aching sensation (4) steady intense griping distress or (5) sharp intermittent knifelike jabbing pain It may involve the entire lower abdomen localize in either the right or left lower quadrant or shift from one site to another Often the distress is relieved by defecation or expulsion of flatus Abdominal distention bloating rumbling and gurgling and the frequent passage of flatus are common symptoms and may be associated with anorexia nausea and excess belching

Constipation one of the major complaints is characterized by infrequent evacuations the expulsion of hard dry small pellets or the passage of long narrow ribbonlike or pencil shaped stools resulting from spasm

Diarrhea occurs in approximately 25 per cent of patients The stools are mushy or semisolid and are passed two or more times daily frequently after meals often with urgency or tenesmus *Excess mucus* may be present but there is no blood loss weight loss or nutritional disturbance

Neurocirculatory or vasomotor instability is manifested by weakness fatigue headaches palpitation faintness excess perspiration hot and cold sensations nausea or "nervousness"

Physical Examination Physical examination usually reveals a well nourished patient with no significant abnormalities The colon may be palpable and tender particularly along the descending colon and sigmoid where a narrow tender sausage shaped mass may be present The abdomen is often tympanitic Findings on rectal examination are usually normal

Diagnosis A wide variety of organic diseases may simulate the irritable colon syndrome because of the broad spectrum and variability of its symptoms The diagnosis can be made only after exclusion of other organic diseases by roentgenography sigmoidoscopy and stool examinations for blood ova parasites and bacterial pathogens The diagnosis of irritable colon is suggested by a long history of intermittent attacks of lower abdominal discomfort associated with constipation diarrhea or the passage of excess mucus in the stools without pus or blood Precipitation of the symptoms by emotional factors relief by bowel movements and flatus a long protracted history of laxative

detailed inquiry Emphasis is also placed upon the mode of onset Diarrhea following emotional upheavals chronic cathartic excess dietary indiscretions or the intake of ice cold or hot beverages is often functional in origin In some instances diarrhea may be caused by antibiotics or drugs When nausea vomiting and fever precede or accompany the abrupt onset of diarrhea the most likely diagnoses are food poisoning gastroenteritis or the specific dysenteries Bacterial viral or parasitic infections should be suspected in epidemic or institutional forms of diarrhea Nocturnal diarrhea frequently occurs with ulcerative colitis and diabetic neuropathy

A history of insidious and progressive constipation or alternating constipation and diarrhea with a change in bowel habit should arouse the suspicion of malignancy although these symptoms may also be present in functional disturbances Gross rectal bleeding is characteristically absent in the functional diarrheas and gastroenteritis but may be the presenting symptom of ulcerative colitis the specific dysenteries rectal carcinoma polyps hemorrhoids and intussusception

Approximately *70 per cent of all rectal tumors* are within reach of the index finger No single examination is more valuable and informative than the digital examination of the rectum In some instances combined abdominorectal or rectovaginal examinations are indicated Abdominal palpation often reveals a narrow tender segment of descending colon which may represent a spastic colon ulcerative colitis diverticulitis or feces Repeated examination after the patient evacuates his colon or is given a cleansing enema will aid in excluding "phantom masses" caused by fecal material A persistent mass in the left lower quadrant is suggestive of malignancy diverticulitis or a localized inflammatory process a right side mass is often found with cancer of the right colon regional enteritis granulomatous tumors (amebic or tuberculous) and intussusception

Inspection of the stools is helpful in distinguishing gross bleeding from blood streaking on the surface of the stool usually caused by hemorrhoids Black tarry stools usually signify bleeding from the upper gastrointestinal tract The detection of occult blood by the benzidine dihydrochloride test may offer a useful routine screening procedure for malignancy The presence of persistent occult blood in the stools warrants a careful search for polyps and cancer The cytologic technique for demonstrating tumor cells may be a helpful adjunct Repeated examinations of warm stools for ova parasites and bacterial pathogens are essential in unexplained diarrhea or rectal bleeding

The proctosigmoidoscope and roentgenogram are the most accurate methods (95 per cent) of establishing the diagnosis of colonic and rectal disease The lower 10 to 12 in of the rectum and rectosigmoid areas which are the most difficult to examine roentgenographically are best seen through the proctosigmoidoscope Approximately *70 per cent of cancers of the large bowel* and *90 per cent of rectal and rectosigmoid tumors* can be visualized and diagnosed by this means Indications for the procedure are (1) abdominal complaints in patients over forty particularly where malignancy may be suspected (2) persistent or intermittent diarrhea (3) rectal bleeding or occult blood in the stools (4) unexplained anemia or weight loss (5) symptoms of chronic large bowel obstruction (6) rectal pain (7) presence of a left lower quadrant abdominal mass and (8) as a preliminary to rectal surgery particularly for hemorrhoids or rectal fistulas

Routine proctosigmoidoscopy for all patients over forty years of age as a screening procedure to detect early cancer or precancerous lesions has been advocated particularly since polyps are found in 6 to 8 per cent of all patients sigmoidoscoped routinely The examination is also exceedingly valuable in following the course of ulcerative colitis and other inflammatory processes in obtaining culture material in the parasitic and dysentery diseases and in procuring biopsy material

The roentgen examination is the only satisfactory method for examining the entire colon and is indicated in all patients with colonic symptoms but it should be preceded by a careful history and by a physical and proctosigmoidoscopic examination. The diagnosis of a functional disorder is not tenable until organic disease is excluded by these procedures

IRRITABLE COLON SYNDROME

The irritable colon syndrome may be defined as a symptom complex caused by abnormal irritability or neuromuscular imbalance of the colon sufficiently severe to produce colonic dysfunction and abdominal distress The highly variable clinical expressions of this syndrome have been described as spastic colon unstable colon colonic neurosis mucous colitis cathartic colitis nervous indigestion dyspepsia functional colitis spastic constipation nervous diarrhea or asynergia of the colon, depending upon which phase of altered motor or secretory function predominates The term *colitis* is not justified since there is no known inflammatory or organic component in this syndrome

Etiology Emotional disturbances tensions and life stresses are the most common denominators Colonic dysfunction has been attributed to imbalance of the autonomic nervous system in emotionally unstable tense anxious apprehensive intro

Symptoms Constipation may be accompanied by abdominal discomfort backache general abdominal distention anorexia belching and the passage of flatus At times liquid feces may be passed around the impaction presenting the paradoxical symptoms of diarrhea With excessive straining at stool hemorrhoids mucosal abrasions anal fissures or fistula in ano may develop

Treatment The management of rectal constipation is similar to that of the irritable colon Organic disease should be excluded by physical examination proctosigmoidoscopy and barium enema before instituting therapy Treatment consists of (1) establishment of a definite bowel habit at a time of the day when the patient can relax particularly after breakfast when the most active gastrocolic reflex occurs (2) dietary care as described previously with adequate fruits vegetables and fluids (3) avoidance of routine cathartics and enemas (4) abdominal exercises (5) antispasmodics and (6) reassurance that a daily evacuation is desirable but not essential to good health

If constipation persists during the early period of treatment mild cathartics (milk of magnesia 30 to 60 ml) or enemas of water physiologic saline solution (1 tsp of salt to a quart of water) or oil (60 to 90 ml warm olive oil as a retention enema) every 2 to 4 days may be necessary until spontaneous evacuations appear Glycerin rectal suppositories are often helpful The patient must be constantly reassured that no organic disease exists

Removal of fecal impactions is often necessary in the bedridden patient Ointment or jelly is instilled into the anal canal the anus is dilated with the fingers and the impaction is broken up digitally and removed Approximately 90 to 120 ml warm olive oil is then administered rectally as a retention enema and is followed later by a tap water enema

CONSTIPATION AND DIARRHEA

A further discussion of constipation and diarrhea is presented in Chap 16

NONSPECIFIC ULCERATIVE COLITIS

This form of colitis is characterized by a diffuse ulcerative inflammation of the colon which cannot be ascribed to any known single cause and is manifested by bloody diarrhea often accompanied by generalized systemic symptoms The idiopathic form of ulcerative colitis must be distinguished from ulcerative colitis of specific etiology such as that associated with tuberculosis amebic or bacillary dysentery lymphopathia venereum vitamin deficiency and uremia discussed elsewhere (Chaps 19 123 188 194)

Incidence Among chronic intestinal diseases ulcerative colitis is relatively common and appears to be increasing in frequency It is found equally among men and women and may occur in childhood but is most common in the second third and fourth decades

Etiology and Pathogenesis The cause of nonspecific ulcerative colitis is unknown Various bacteria implicated in the disease have proved to be secondary invaders (alpha and beta streptococci staphylococci diplococci *Bacillus necrophorus*) Viruses allergic factors and nutritional deficiencies do not appear to play significant etiologic roles Bacillary and amebic dysentery are precursors in only a small percentage of patients The irritable colon does not predispose to ulcerative colitis

Lysozyme a mucolytic enzyme has been suggested as a causative agent in view of the high titer found in the stools of patients with this disease It was postulated that lysozyme removed the protective colonic surface mucus favoring ulceration of the denuded mucosa by proteolytic enzymes such as trypsin Lysozyme however does not play a significant role in the pathogenesis of ulcerative colitis It serves as a measure of the activity of the disease and the extent of the inflammatory reaction and is found in considerable amounts in pus and granulation tissue Lysozyme moreover cannot digest or dissolve colonic mucus and various antilysozyme agents particularly detergents which inhibit the enzyme do not alter the course of the disease

Emotional conflicts anxiety and resentment are often associated with exacerbations and recurrences of the disease and are manifested by vascular motor and secretory abnormalities of the colon mediated presumably through the autonomic nervous system There is no conclusive evidence however that a specific personality trait predisposes to the disease or that the disease is exclusively a psychosomatic process

The generalized systemic nature of the disease the associated arthritis and erythema nodosum like lesions the submucosal inflammatory reaction and the changes in the ground substance of the basement membrane of the epithelial cells suggest that nonspecific ulcerative colitis may fall in the group of collagen diseases

Pathology The most striking change is found in the mucosa and submucosa of the colon and rectum The entire lining is often involved in a diffuse severe process of ulceration inflammation and congestion As the disease progresses the mucosa becomes thickened and more diffusely ulcerated Coalescence of the ulcerations may lead to denudation of the mucosal surface resulting in thinning of the bowel and susceptibility to perforation Linear longitudinal ulcers extend along or between the

abuse or the enema habit often characterize the clinical picture

The proctosigmoidoscopic examination is essentially normal or may reveal spasm at the rectosigmoid narrowing of the lumen or excessive mucus secretion Roentgen examination by barium enema is often normal or presents rapid filling of the colon increased segmentation or an accordionlike appearance of the transverse colon A contracted spastic descending colon and sigmoid may appear as a straight narrow tube without haustral markings

Differential Diagnosis Carcinoma of the colon diverticulitis ulcerative colitis regional enteritis the specific dysenteries acute appendicitis carcinoma of the stomach or pancreas duodenal ulcer and gallbladder disease may produce symptoms simulating those of the irritable colon

Treatment Treatment of the patient with an irritable colon involves psychologic rehabilitation dietary care and the use of antispasmodics and mild sedatives

Successful treatment depends upon a close rapport between the physician and patient Situations of conflict and stress occupational difficulties social financial sexual and environmental problems should be discussed freely and related to the presenting complaints The patient is given insight into the mechanisms by which emotional tensions fears anxiety and hostility express themselves The diagnostic procedures are discussed in detail to allay the patient s anxiety concerning organic disease such as cancer and ulcerative colitis Every effort is made to prevent the patient from becoming bowel conscious Intensive psychotherapy is rarely necessary

Dietary management consists of the administration of a bland diet containing liberal amounts of meat fish chicken eggs cheese cooked fruits and cooked vegetables (similar to the Ulcer Diet IV in Table 126 described in Chap 245) Raw fruits raw vegetables and coarse foods are eliminated since they may initiate increased peristaltic activity and spasm "Gassy" foods (high in carbohydrate or cellulose) such as honey candy syrups cabbage cauliflower potatoes coleslaw radishes onions cucumbers tomatoes broccoli squash and turnips are restricted Ice cold or hot liquids which may induce spasm should be avoided Coffee and alcoholic beverages are usually limited

During periods of diarrhea all fruits and vegetables are eliminated and tobacco excess which often stimulates intestinal activity is prohibited The constipated patient is instructed to add two or three servings of both cooked fruits and cooked vegetables to the daily diet including liberal servings of spinach and prunes Adequate water intake is essential Laxatives and enemas should be discontinued and bowel regulation encouraged by establishing a definite time for evacuation In some instances milk of magnesia (15 to 60 ml) is effective as a temporary measure An occasional tap water or oil retention enema may be necessary early in the management to prevent rectal impaction

Antispasmodics are valuable adjuncts in the management of the irritable colon Tincture of belladonna (10 to 15 drops three or four times daily) and atropine (0 3 to 0 6 mg four times daily) are the most satisfactory The clinical superiority of Banthine or Neo banthine over adequate doses of atropine has not yet been proved Phenobarbital (0 15 to 0 03 Gm three or four times daily) and the tranquilizing drugs are also helpful particularly in the anxious patient Morphine should be avoided since it often increases intestinal spasm In instances of severe pain or intractable diarrhea codeine (0 03 to 0 06 Gm) or paregoric (5 to 10 ml) may be used Kaolin bismuth and bulk cathartics are not recommended Vitamin supplements may be necessary

RECTAL CONSTIPATION (*Dyschezia*)

Rectal constipation (simple constipation) results primarily from a failure of the defecation reflex The transport of feces through the colon proceeds at a normal rate until the feces enter the rectum When the defecation reflex is ignored or fails to appear feces accumulate in the rectum and become dehydrated and often impacted

Etiology and Pathogenesis Rectal constipation is one of the most common complaints of civilized man Voluntary inhibition of the defecation reflex is the most frequent cause It is accomplished by forcible contraction of the external anal sphincter and relaxation of the muscles of the anterior abdominal wall aided by thoracic breathing Defecation is thus forcibly avoided until mass peristalsis is completed When segmentation begins again there is further dehydration and reduction in the size of the fecal contents The walls of the rectum become adapted to the fecal contents and the sensation of fullness and distention disappears

Inhibition of the defecation reflex is established early in life as part of the toilet training of the infant and continues throughout life as a result of the exigencies of daily living This disruption of a regular habit pattern is further accentuated by fatigue emotional disturbances and anxiety regarding daily evacuation Pain in the rectum from hemorrhoids or fissures encourages further voluntary inhibition of defecation Other causes are lack of exercise atony of the rectum immobilization in bed and weakness or injury of the pelvic and abdominal muscles resulting from pregnancy or ascites

The small intestine should be examined by a barium meal to detect associated areas of involvement

Differential Diagnosis Warm fresh stools and rectal swabs should be cultured for pathogenic organisms and a careful search made for *Endamoeba histolytica* Amebic ulcers appear as sharply punched out discrete irregular undermined lesions separated by normal mucosa differing from the diffuse granular ulcerated appearance characterizing nonspecific ulcerative colitis *Bacillary dysentery* is distinguished by the demonstration of specific dysentery organisms Proctitis and sigmoiditis of *lymphogranuloma venereum* may be identical proctoscopically with nonspecific ulcerative colitis but lymphopathia venereum is characterized by a history of enlarged inguinal glands predilection for the female the presence of rectal stricture hyperglobulinemia and a positive Frei test Primary *tuberculosis* of the intestinal tract usually involves the cecum and ascending colon and is often associated with pulmonary tuberculosis *Regional enteritis* is less likely to produce gross blood in the stools and presents a characteristic roentgen picture and a normal mucosa on sigmoidoscopic examination *Diverticulitis* of the colon may produce some of the symptoms of ulcerative colitis but is easily distinguished roentgenologically and usually occurs in an older age group *Malignancies* of the colon are differentiated by roentgen and sigmoidoscopic examinations *Uremic colitis* is readily recognized by the accompanying clinical and laboratory evidence of renal failure

Complications Complications include pseudopolyp formation malignant degeneration rectal strictures perforation with localized or generalized peritonitis hemorrhage and perianal or rectal fistulas and abscesses Other complications are acute arthritis erythema nodosum anemia thrombophlebitis or thrombosis of the veins of the extremities hypoproteinemia clubbing of the fingers fatty liver amyloid disease retarded sexual and physical development uveitis amenorrhea and marked electrolyte unbalance

Cancer occurs in 3 to 10 per cent of patients particularly if the ulcerative process remains active for a period of 10 years or longer

Medical Management There is no specific treatment for this disease Emotional and physical rest are essential to the healing of the diffuse inflammatory process Attention to the patient s emotional problems and dietary care are directed toward decreasing gastrointestinal activity Bed rest and hospitalization are usually necessary It is often advisable to restrict visitors and members of the family who may disturb the patient emotionally

Psychotherapy The principles of the psychotherapeutic approach are similar to those discussed under Irritable Colon Syndrome Successful therapy depends in part upon the physician s ability to instill confidence and hope in the anxious resentful frustrated acutely ill patient Every effort should be directed towards rehabilitating the patient and returning him to an active normal life with a minimum of restriction as soon as possible Active psychotherapy during the acute phase often aggravates the disease and is contraindicated Most emotional problems are best handled by the attending physician In selected instances however formal psychiatry may be helpful in the subacute or chronic phase

Fig 181 Acute stage of ulcerative colitis involving the entire colon Note diffuse ulceration and irregular saw-toothed appearance of the rectum sigmoid and entire colon accompanied by shortening narrowing and loss of haustration.

Diet A high calorie high protein bland diet adequate in minerals and vitamins (similar to that prescribed under Irritable Colon Syndrome Treatment) is recommended Fruits and vegetables as well as fruit juices are avoided in the presence of diarrhea Frequent interval feedings containing protein supplements are prescribed Ice cold fluids and tobacco are excluded since they may stimulate intestinal motility The diet is supplemented with vitamins either orally or parenterally particularly vitamin K and vitamin C The patient s weight and calorie intake are followed carefully

tenial muscle landmarks Polypoid hyperplasia and regeneration may be found in some areas The submucosal and muscular layers are inflamed early and subsequently undergo fibrosis and contraction resulting in marked narrowing of the lumen

The inflammatory process in general is exudative and reparative without any granulomatous tendencies It may be nonspecific in origin or arise from the submucosal coalescence of mucosal crypt abscesses or from intestinal infarction caused by a necrotizing vasculitis resembling periarteritis nodosum and thromboangiitis obliterans

The rectum and sigmoid are the most common sites of involvement the descending and transverse colons are next most frequently ulcerated and the cecum least often Extension of the ulcerative process to the ileum may occur in approximately one third of cases Segments of the small intestine may also be involved Ulcerative colitis restricted to the right side of the colon is uncommon Regional enteritis and ulcerative colitis are two distinct morphologically distinguishable diseases

Symptoms The onset of ulcerative colitis may be either sudden or insidious Its course may be slowly progressive chronic and irregular with exacerbations and remissions or rapid and fulminating particularly in younger individuals The disease tends to be chronic and irreversible A few patients are cured permanently if the ulceration is localized to the rectum or sigmoid The remainder are affected intermittently for life

The clinical picture depends upon the site extent and severity of the inflammatory process When the disease is limited to the rectum or rectosigmoid the onset may be gradual and the only presenting symptom is the passage of red blood and mucus in the stool accompanied by constipation or diarrhea The stools at first may be well formed hard and dry As the disease progresses the number of evacuations may reach 15 to 20 or more daily with rectal incontinence of a serous exudate containing red blood pus mucus and gas associated with tenesmus and abdominal cramping pain Fever may persist for days or weeks loss of appetite is common and weight loss extreme Nausea and vomiting occur only occasionally and abdominal distress may be absent in some instances

In the chronic phase the patient passes two to five semisolid or watery stools daily often with gross blood and appears anemic and malnourished Repeated remissions and exacerbations over a period of years may result in chronic disability

In the severe fulminating form the onset is abrupt with continuous loose watery explosive stools containing gross blood gas and mucus accompanied by high fever tachycardia complete anorexia weakness severe anemia and profound debility Death may result from perforation generalized peritonitis massive hemorrhage inanition and severe electrolyte imbalance

Diagnosis The history of frequent liquid evacuations containing blood mucus and pus in a patient whose stools are free of specific pathogens or parasites suggests the diagnosis of nonspecific ulcerative colitis Sigmoidoscope and roentgen examinations establish the diagnosis when the patient can safely undergo these procedures

Since the mucosa of the rectum or rectosigmoid is involved in approximately 90 per cent of patients with ulcerative colitis the diagnosis may be made by proctosigmoidoscopic examination in the vast majority of patients often before an abnormality is discernible by roentgen examination In the severe acute fulminating type sigmoidoscopy and roentgen examination should be deferred until pain fever spasm and irritability have diminished

The examinations must be performed with care Cleansing soapsuds enemas and cathartics as preparation for sigmoidoscopy and roentgen examination are contraindicated because of the danger of perforation or hemorrhage

Sigmoidoscopic Examination The appearance of the rectum and sigmoid depends upon the severity of the disease During the acute phase the rectal mucosa appears edematous and engorged presenting excess mucus and many minute superficial pin point bleeding areas Swabbing with cotton reveals a diffusely granular freely bleeding friable mucosa Visualization of the ulcerations depends upon the degree of mucosal edema Later in the disease the ulcerations and denudation may be extensive and are accompanied by a thick mucopurulent sanguineous exudate In the chronic state the mucosa appears thickened pale firm and granular The lumen may be narrow and the normal mucosal architecture is absent or distorted Pseudopolyps may be seen in the rectum or sigmoid

Roentgen Examination of the Colon The roentgen appearance of the barium enema does not always parallel the severity of the process and may be normal early in the disease when the sigmoidoscopic examination presents the classical appearance of diffuse ulceration The earliest findings are those of a fine irregular serrated or saw toothed appearance of the barium filled segment commonly associated with spasm and irritability (Fig 181) With extensive involvement the normal mucosal pattern is distorted grossly irregular or absent Areas of polypoid hyperplasia appear as circular irregular filling defects As the disease progresses the haustrations disappear and the colon appears shortened and the lumen narrowed giving the classical lead pipe appearance (Fig 182) Involvement of the terminal ileum is indicated by rigidity narrowing or dilatation and distortion of the mucosal pattern

The beneficial effects of steroid therapy and the fall in fecal lysozyme titer may be attributed in part to a decrease in the extensive inflammatory process within the tissue as well as the diminution of the systemic and toxic manifestions

Remissions induced by hormone therapy are not permanent Relapses and reactivation of the disease are seen in 75 to 80 per cent of patients at varying intervals after steroid treatment is discontinued Long term hormone therapy however may effectively sustain patients in a satisfactory remission for prolonged periods of time and is helpful in preventing chronic invalidism

During the acute phase of the disease adrenocorticotropic hormone is administered intravenously in doses of 20 mg daily in 500 ml glucose and water as an 8 hr continuous drip or intramuscularly (20 to 30 mg as the purified gel twice daily) for 7 to 14 days Cortisone may also be useful in inducing a remission and is prescribed intramuscularly (200 to 300 mg daily) or orally (50 to 75 mg four times daily) After 7 to 14 days the dose of hormone may be gradually reduced as clinical improvement becomes evident

Sulfonamides or antibiotics should be administered in conjunction with hormone therapy Gantrisin or sulfadiazine (1 0 Gm four times daily) is adequate in the milder forms of the disease In the presence of sepsis or peritonitis streptomycin and penicillin are preferable Potassium chloride (1 0 Gm orally two to three times daily) is recommended particularly in the acute phase of the disease to compensate for the urinary and fecal loss Blood transfusions vitamins sedatives antispasmodics and antacids are administered as required

Once a satisfactory remission has been induced cortisone may be given orally for prolonged periods of time Patients have been maintained on hormone therapy for 2 years or longer The usual maintenance oral dose of cortisone varies from 75 to 150 mg a day in three divided doses of 25 to 50 mg Long term cortisone therapy is supplemented by oral sulfonamides or antibiotics intermittently potassium chloride vitamins antispasmodics and dietary care

Cortisone therapy should not be terminated abruptly The dose is tapered gradually before discontinuation to prevent adrenal suppression With prolonged hormone therapy it may be advisable to activate the adrenal cortex intermittently at 6 to 9 month intervals by brief periods of adrenocorticotropic hormone stimulation

Perforation and hemorrhage are exceedingly rare complications following steroid therapy Gastrointestinal ulceration does not present a significant problem in this group of patients although a pre existing peptic ulcer should be excluded before instituting long term hormone therapy Antacids and interval feedings may be prescribed to prevent gastric complications Psychic disturbances are encountered rarely if the patient is maintained on small doses of phenobarbital and is under careful surveillance for undue excitement or overstimulation

Surgery Surgical intervention is necessary in 10 to 15 per cent of patients Indications for surgery are (1) rectal stricture (2) perianal fistula and abscess (3) intractable diarrhea anemia and malnutrition (4) recurrent massive hemorrhage (5) pseudopolyposis (6) malignant change and (7) complications such as arthritis and pyoderma gangrenosum Because of the danger of malignant degeneration surgery should be recommended in the presence of long continued persistent activity of the ulcerative process over a period of 10 years or more

Ileostomy with subsequent colectomy is the surgical procedure of choice Recently subtotal or total colectomy in one stage with ileostomy has been recommended Many of these surgical procedures may now be performed as elective rather than emergency procedures as a result of the judicious use of steroid hormones and other supportive measures

Prognosis The over all surgical and medical mortality in ulcerative colitis approximates 10 per cent The disease tends to be chronic and is characterized by frequent exacerbations and remissions Permanent remission after the initial attack is uncommon Satisfactory rehabilitation may be anticipated in 65 to 75 per cent of patients treated by conservative means The disease presents a milder course in older individuals

DIVERTICULOSIS AND DIVERTICULITIS

Diverticula of the colon are abnormal outpouchings or sacculations which may occur throughout the gastrointestinal tract and are most common (80 per cent) in the sigmoid colon (Fig 184) (Meckel s diverticulum is described in Chap 246) Diverticula of the large intestine are found in 5 per cent of individuals over forty years of age increasing in frequency with each decade past middle life Most diverticula are multiple and are of the false variety consisting of mucosa and serosa, presumably acquired in origin although true diverticula containing all the coats of the bowel wall may be found

Diverticulosis usually refers to noninflammatory uncomplicated diverticula When inflammation occurs in one of these pouches (10 to 20 per cent) the term *diverticulitis* is applied Diverticulitis usually involves the sigmoid colon may be acute or chronic and is seen more frequently in men

Fig 182 Chronic stage of ulcerative colitis in a 50 year old woman with a 20 year history Her presenting symptoms were diarrhea and severe blood loss The colon is narrow and tubular presenting a lead pipe appearance with absence of haustration A discrete pseudopolyp revealing epithelial hyperplasia was found in the transverse colon

Supportive Measures The free use of blood transfusions contributes significantly to the medical management Intravenous dextrose solutions protein hydrolysates and the parenteral administration of albumin may be helpful Correction of fluid and electrolyte imbalance (particularly potassium and chloride loss) is essential Tincture of belladonna (10 to 30 drops four times daily) or atropine (0 6 to 1 mg four times daily) is administered to diminish intestinal motility Phenobarbital (0 03 Gm four times daily) is also helpful as a general sedative Codeine (0 03 Gm) or small doses of tincture of opium helps control the diarrhea and abdominal discomfort Bismuth subcarbonate and kaolin are not effective over a prolonged period of time

Sulfonamides and Antibiotics The sulfonamides and antibiotics are not specific for the disease and do not alter its course They may be effective however in decreasing secondary infection and diminishing the total bacterial content of the feces particularly in the acute septic phase of the disease Sulfadiazine and Gantrisin (either one in doses of 1 Gm four to six times daily) are the most satisfactory sulfonamide preparations and are preferable to the nonabsorbable drugs such as Sulfasuxidine since they afford greater penetration through the entire bowel wall A number of other sulfonamide drugs including azopyrin (1 0 Gm six times daily) have been recommended Streptomycin given orally or parenterally has only a transitory effect on the fecal flora therapeutic results with chloramphenicol and Terramycin are not impressive Aureomycin usually aggravates the diarrhea Penicillin may be valuable particularly in the presence of gram positive organisms When perforation of the bowel is suspected a combination of antibiotics such as penicillin and streptomycin may be lifesaving

Hormone Therapy The adrenal steroids are valuable adjuncts in the therapy of ulcerative colitis Hormone therapy does not constitute a cure but may induce remissions when administered in adequate dosage and properly integrated with the general medical regimen It is particularly indicated (1) in the acute fulminating phase of the disease associated with systemic manifestations (2) during the acute exacerbations in the chronic stage when complications are not present (3) as a preoperative measure in patients requiring ileostomy and (4) as long term maintenance therapy in chronic intractable colitis Steroid therapy is usually not necessary in the mild form of the disease

No significant sustained therapeutic hormonal response may be anticipated in the presence of extensive cicatrization of the colon rectal strictures perianal fistulas abscess formation or perforation with peritonitis although steroid therapy is often valuable in preparing patients with these complications for ileostomy

Following the administration of adrenocorticotropic hormone or cortisone and coincident with the induced remission there is a consistent and prompt fall in the fecal lysozyme titer to levels characteristic of the remission phase (Fig 183)

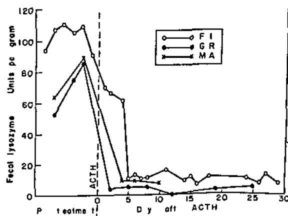

Fig 183 Effect of ACTH upon the fecal lysozyme titer in three patients (F I G R and M A) with ulcerative colitis Note the prompt fall in the fecal lysozyme titer within 5 days following the administration of ACTH accompanying the clinical remission

enth decades although it may be seen in child hood and adolescence

Etiology The polyp is regarded as the most common precursor of colonic and rectal cancer Malignant transformation of single or multiple polyps has been definitely established Regenerating areas of epithelial hyperplasia in chronic ulcerative colitis may also undergo malignant degeneration There is no evidence that diverticulosis parasites constipation or hemorrhoids predispose to cancer A hereditary tendency however probably exists in view of the familial incidence of the disease

Pathology Approximately 75 per cent of all large bowel malignancies involve the left colon The rectum rectosigmoid and sigmoid flexure are the most common sites of colonic involvement (65 to 70 per cent) followed by the cecum and ascending colon descending colon transverse colon hepatic flexure and splenic flexure in order of frequency Multiple primary carcinomas of the colon may occur but are not common (3 to 4 per cent)

The vast majority (95 per cent) of malignancies of the colon are adenocarcinomas the remainder are epitheliomas usually of the squamous cell type involving the anus Sarcomas of the lymphomatous variety and malignant melanomas are rare

Adenocarcinomas of the colon may be divided into four types (1) medullary (2) scirrhous (3) colloid and (4) papillary The ulcerating fungating cellular *nodular* or *medullary* tumor projecting into the lumen or encircling the bowel is the most common In the left colon the small "napkin ring *scirrhous* variety with predominant scar tissue formation produces a firm contracting tumor (Fig 185) Large *colloid* tumors containing mucinous or gelatinous material with little evidence of cellular activity occur in approximately 5 per cent of all malignant tumors and are most common in the cecum and ascending colon *Papillary* carcinomas are usually seen in the left side of the colon

The largest tumors (medullary and colloid) often occur in the cecum and proximal colon Medullary tumors in the distal colon however are usually smaller because of scar tissue contraction and may cause partial obstruction perforation abscess formation or fistulas Carcinomas of the narrower distal colon are often scirrhous and may also produce obstruction by encircling the lumen with cicatricial tissue

Broders classification of malignancy estimates the rapidity of growth and early invasion by dividing tumors into four groups depending upon the degree of cell differentiation The more differentiated and less malignant types of tumor (grades 1 and 2) are found in approximately 75 per cent of carcinomas of the colon Epitheliomas are highly malignant (grade 3) and metastasize early as do sarcomas and melanomas The colloid cancer grows slowly and metastasizes late although regional lymphatic extension is common and widespread

Metastases occur most commonly by way of the lymphatics involving the regional lymph nodes liver and lungs most frequently Colonic tumors also spread by direct extension or through the blood stream Metastases may reach the brain directly through the paravertebral veins

Symptoms Cancer of the colon and rectum presents no characteristic symptoms in the early stages The patient is often completely asymptomatic Vague abdominal distress flatulence and constipation may be discernible but are minimal so that 9 to 12 months usually elapse between the onset of symptoms and the diagnosis The presenting complaint depends upon the site of the lesion the nature and extent of the tumor and complications such as ulceration perforation obstruction or metastasis

The symptoms of the left and right halves of the colon may be indistinguishable or may differ considerably depending upon the stage of the disease and the type of tumor In the left half of the colon the symptoms are usually obstructive in nature since the tumors are constricting in type the fecal contents are more solid and the lumen narrower (Fig 185) Carcinoma of the right half of the colon rarely causes obstruction because the fecal stream is liquid the tumors are softer and the diameter of the colon is larger Tumors in this area are more likely to produce (1) vague abdominal distress (2) anemia or weakness and (3) an abdominal mass The transverse colon is an area of transition in which the colonic contents change from liquid to semisolid Consequently tumors in this area present symptoms of either the right or left colon or both

Carcinoma of the Left Half of the Colon The predominating symptoms are those of *obstruction* resulting from encroachment upon the lumen of the bowel The earliest warning may be a change in bowel habit which in itself is not pathognomonic but is usually sufficiently significant to warrant suspicion of malignancy Other early symptoms simulating those of the irritable colon are constipation diarrhea flatulence and abdominal distress As the obstruction progresses cramping or colicky abdominal pain borborygmi and distention ensue Progressive constipation or obstipation is common Gross blood in the stool may appear in the advanced stage but anemia is not so common nor so severe as in carcinoma of the right colon Weight loss is a late sign

Lesions of the rectum may produce increasing constipation diarrhea rectal pain or a feeling of

FIG 184 Roentgenologic appearance of colon following subsidence of an attack of acute diverticulitis Several diverticula are present in the sigmoid Site of involvement is indicated by arrows

Etiology The cause of diverticula formation is unknown An inherent weakness at the point at which the blood vessels pierce the intestinal wall has been implicated Excess fat may be a contributing factor Diverticulosis is alleged to occur in sedentary obese constipated individuals and is seen equally among men and women The high incidence of diverticula in the sigmoid has been attributed to anatomic fixation of this area making it more susceptible to changes in intraluminal pressure

Symptoms Diverticula produce no significant symptoms other than those associated with an irritable colon constipation or inflammation

The symptoms of diverticulitis are caused by inflammation of the diverticula or obstruction of the colon resulting from the inflammatory reaction and scar tissue formation The characteristic symptoms of acute diverticulitis are abdominal pain usually localized to the left lower quadrant accompanied by signs of peritoneal irritation localized muscle spasm fever and leukocytosis Diverticulitis of the sigmoid is frequently referred to as left sided appendicitis Inflamed diverticula in the cecum or ascending colon may simulate acute appendicitis The acute *inflammatory process* may subside or progress to perforation abscess or fistula formation peritonitis or obstruction Constipation or alternating diarrhea and constipation is common Gross bleeding occurs in 10 to 20 per cent of patients Hemorrhage may be massive in rare instances

Obstruction of the colon is caused by edema infection fibrosis or angulation at the site of the diverticulitis Recurrent cramplike abdominal pain in the left lower quadrant tenderness protective muscle spasm and distention produce a clinical picture resembling that of carcinoma of the large bowel Approximately one third of patients develop an inflammatory mass palpable either by abdominal or rectal examination

Diagnosis The diagnosis may be established by the roentgenologic demonstration of diverticula (Fig 184) or a localized ragged saw tooth distortion of the mucosal pattern of the colon The differentiation between carcinoma and obstructive diverticulitis by roentgenologic criteria may be difficult Diverticulitis does not predispose to malignancy although the two conditions may exist coincidentally The problem is not that of diverticulitis developing into carcinoma but the inherent difficulty in the differential diagnosis

Treatment Diverticulosis requires no specific therapy other than correction of constipation and the treatment of the irritable colon A bland diet free of coarse fibers and seeds and mineral oil may be prescribed

Acute diverticulitis is treated by bed rest application of heat to the abdomen and sulfonamides penicillin or streptomycin or a combination of these Antispasmodics such as atropine (0 6 mg four times daily) are administered *to the point of* tolerance A soft bland diet is recommended
